The prototypic nonconvulsive generalized seizure is the *typical absence seizure* in children (formerly called petit mal). These seizures begin abruptly, usually last less than 10 seconds, are associated with cessation of all motor activity, and result in loss of consciousness but not loss of posture. The patients appear as if in a trance, but the episodes are so brief that their occurrence can be missed by a casual observer. Unlike a focal seizure there is no aura before the seizure or confusion after the seizure (the postictal period). Patients may exhibit mild motor manifestations such as eye blinking but do not fall or have tonic-clonic movements. Typical absence seizures have very distinctive electrical characteristics on the electroencephalogram (EEG).

Other types of generalized seizures can involve only abnormal movements (myoclonic, clonic, or tonic) or a sudden loss of motor tone (atonic). The most common convulsive generalized seizure is the tonic-clonic (formerly called grand mal seizure). Such seizures begin abruptly, often with a grunt or cry, as tonic contraction of the diaphragm and thorax forces expiration. During the tonic phase the patient may fall to the ground in a rigid posture with clenched jaw, lose bladder or bowel control, and become blue (cyanotic). The tonic phase typically lasts 30 seconds before evolving into clonic jerking of the extremities lasting 1 to 2 minutes. This active phase is followed by a postictal phase during which the patient is sleepy and may complain of a headache and muscle soreness.

A primary generalized tonic-clonic seizure can be difficult to distinguish on purely clinical grounds from a secondarily generalized tonic-clonic seizure with a brief aura. This distinction is not simply academic; it can be vital to choosing proper treatment as well as pinpointing the underlying cause.

Epilepsy Is the Chronic Condition of Recurrent Seizures

Recurrent seizures constitute the minimal criterion for the diagnosis of epilepsy. The oft-quoted clinical rule emphasizes this point: "A single seizure does not epilepsy make." Various factors that contribute to a clinical pattern of recurrent seizures—the underlying etiology of the seizures, the age of onset, or family history—are ignored in the seizure classification scheme in Table 50–1. The classification of the epilepsies initially evolved primarily based upon clinical observation rather than a precise cellular, molecular, or genetic understanding of the disorder. The factors influencing seizure type and severity were sometimes recognized as patterns of symptoms, referred to as the *epilepsy syndromes*.

In the 1989, according to the International League Against Epilepsy (ILAE) classification of the epilepsies, the primary variables were whether or not a focal brain abnormality could be identified (localizationrelated versus generalized epilepsies), and whether or not a cause could be identified (symptomatic versus idiopathic). Most adult-onset epilepsies could be classified as symptomatic localization-related epilepsy, a category that included such causes as trauma, stroke, tumors, and infections. However, many patients have adult-onset epilepsies without a clearly defined cause. Thus, despite the usefulness of this scheme, many types of epilepsy did not fit neatly into its categories. In 2010 the ILAE recommended focusing on the underlying causes of epilepsies based on three broad variables genetic, structural/metabolic, and unknown—as well as a list of electroclinical syndromes. One expects and hopes that these classifications will be elaborated as knowledge of the underlying causes increases.

The Electroencephalogram Represents the Collective Behavior of Cortical Neurons

Because neurons are excitable cells, it should not be surprising that seizures result either directly or indirectly from a change in the excitability of single neurons or groups of neurons. This view dominated early experimental studies of seizures. Electrical recordings of brain activity can be made with intracellular or extracellular electrodes. Extracellular electrodes sense action potentials in nearby neurons and can detect the synchronized activity of ensembles of cells called *field potentials*.

At the slow time resolution of extracellular recording (hundreds of milliseconds to seconds) field potentials can appear as single transient changes called *spikes*. These spikes reflect action potentials in many neurons and should not be confused with spikes in single neurons, which are individual action potentials that last only 1 or 2 milliseconds. The EEG thus represents a set of field potentials as recorded by multiple electrodes on the surface of the scalp (Figure 50–1).

Because the electrical activity originates in neurons in the underlying brain tissue, the waveform recorded by the surface electrode depends on the orientation and distance of the electrical source with respect to the electrode. The EEG signal is inevitably distorted by the filtering and attenuation caused by intervening layers of tissue and bone that act in the same way as resistors and capacitors in an electric circuit. Thus the amplitude of EEG signals (measured in microvolts) is much smaller than the voltage changes in a single neuron (measured in millivolts). High-frequency activity in single cells, such as action potentials, is filtered out by the EEG signal, which primarily reflects slower voltage changes across the cell membrane, such as synaptic potentials.

Although the EEG signal is a measure of the extracellular current caused by the summated electrical activity of many neurons, not all cells contribute equally to the EEG. The surface EEG reflects predominantly the activity of cortical neurons in close proximity to the EEG electrode. Thus deep structures such as the hippocampus, thalamus, or brain stem do not contribute directly to the surface EEG. The contributions of individual nerve cells to the EEG are discussed in Box 50–1.

The surface EEG shows patterns of activity—characterized by the frequency and amplitude of the electrical activity—that correlate with various stages of sleep and wakefulness (see Chapter 51), and with some pathophysiological processes such as seizures. The normal human EEG shows activity over the range of 1 to 30 Hz with amplitudes in the range of 20 to

100 μV. The observed frequencies have been divided into several groups: alpha (8–13 Hz), beta (13–30 Hz), delta (0.5–4 Hz), and theta (4–7 Hz).

Alpha waves of moderate amplitude are typical of relaxed wakefulness and are most prominent over parietal and occipital sites. During intense mental activity, beta waves of lower amplitude are more prominent in frontal areas and over other regions. Alerting relaxed subjects by asking them to open their eyes results in so-called desynchronization of the EEG with a reduction in alpha activity and an increase in beta activity (Figure 50–1B). Theta and delta waves are normal during drowsiness and early slow-wave sleep; if present during wakefulness, these waves are a sign of brain dysfunction.

As neuronal ensembles become synchronized, as when a subject relaxes or becomes drowsy, the summated currents become larger and can be seen as abrupt changes from the baseline activity. Such *paroxysmal* activity can be normal; for example, episodes of high-amplitude activity (1–2 s, 7–15 Hz) occur during sleep (sleep spindles). However, a sharp wave or EEG spike can also provide a clue to the location of a seizure focus in a patient with epilepsy (Figure 50–4).

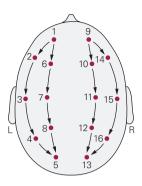

Focal Seizures Originate Within a Small Group of Neurons Known as a Seizure Focus

Despite the variety of clinically defined seizures, important insights into the generation of seizure activity can largely be understood by comparing the electrographic patterns of focal and primary generalized seizures. The defining feature of focal (and secondarily generalized) seizures is that the abnormal electrical activity originates from a *seizure focus*. The seizure focus is nothing more than a small group of neurons, perhaps 1,000 or so, which have enhanced excitability and the ability to occasionally spread that activity to neighboring regions and thereby cause a seizure.

The enhanced excitability (epileptiform activity) may result from many different factors such as altered cellular properties or altered synaptic connections caused by a local scar, blood clot, or tumor. A discrete focus in the primary motor cortex may cause twitching of a finger or jerking of a limb (sometimes called simple partial seizure), whereas a seizure focus in the limbic system is frequently associated with unusual behaviors or an alteration of consciousness (sometimes called complex partial seizure).

The development of a focal seizure can be arbitrarily divided into four phases: (1) the *interictal period* between seizures followed by (2) synchronization of activity

A Standard electrode placement

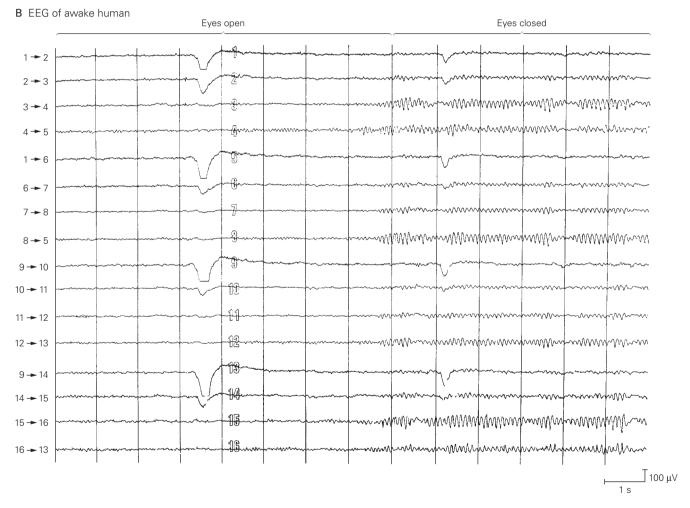

Figure 50–1 The normal electroencephalogram (EEG) in an awake human subject.

A. A standard set of placements (or montage) of electrodes on the surface of the scalp. The electrical response at each site reflects the activity between two of the electrodes.

B. At the beginning of the recording the EEG shows low-voltage activity (circa 20 μV) over the surface of the scalp. The vertical lines are placed at 1 second intervals. During the first

8 seconds the subject was resting quietly with eyes open, then the subject was asked to close his eyes. With the eyes closed, larger-amplitude activity (8–10 Hz) develops over the occipital region (sites 3, 4, 8, 12, 15, 16). This is the normal alpha rhythm characteristic of the relaxed, wakeful state. Slow large-amplitude artifacts occur at 3.5 seconds when the eyes blink and at 9 seconds when the eyes close.

within the seizure focus (Figure 50–4), (3) seizure spread, and finally (4) secondary generalization. Phases 2 to 4 represent the *ictal phase* of the seizure. Different factors contribute to each phase.

Much of our knowledge about the electrical events during seizures comes from studies of animal models of focal seizures. A seizure is induced in an animal by focal electrical stimulation or by acute injection of a convulsant agent. This approach and the development of in vitro brain slice preparations (Box 50–2) have provided a good understanding of electrical events within the focus during a seizure as well as during the interictal period

Neurons in a Seizure Focus Have Characteristic Activity

How does electrical activity in a single neuron or group of neurons lead to a seizure? Each neuron within a seizure focus has a stereotypic and synchronized electrical response called the *paroxysmal depolarizing shift*, an intracellular depolarization that is sudden, large (20–40 mV), and long-lasting (50–200 ms), and triggers a train of action potentials at its peak (Figure 50–7B). The paroxysmal depolarizing shift is followed by an afterhyperpolarization.

The paroxysmal depolarizing shift and afterhyperpolarization are shaped by the intrinsic membrane properties of the neuron (eg, voltage-gated Na⁺, K⁺, and Ca²⁺ channels) and by synaptic inputs from excitatory and inhibitory neurons (primarily glutaminergic and GABAergic, respectively). The depolarizing phase results primarily from activation of AMPA- and NMDA-type glutamate receptor-channels (Figure 50–8A), as well as voltage-gated Na⁺ and Ca²⁺ channels. The NMDA-type receptor-channels are particularly suited to enhancing excitability because depolarization relieves Mg²⁺ blockage of the channel. Once unblocked, excitatory current through the channel increases, thus enhancing the depolarization and allowing extra Ca²⁺ to enter the neuron (see Chapter 10).

The normal response of a cortical pyramidal neuron to excitatory input consists of an excitatory postsynaptic potential (EPSP) followed by an inhibitory postsynaptic potential (IPSP) (because of the basic circuitry shown in Figure 50–8B). Thus the paroxysmal depolarizing shift can be viewed as a massive enhancement of the normal depolarizing and hyperpolarizing synaptic components. The afterhyperpolarization is generated by several types of K^{+} channels as well as a GABA receptor-mediated Cl^{-} conductance (ionotropic GABA_A receptors) and K^{+} conductance (metabotropic GABA_B receptors) (Figure 50–8A). The Ca^{2+} entry through voltage-dependent Ca^{2+} channels and

NMDA-type receptor-channels triggers the opening of calcium-activated channels, particularly K⁺ channels. The afterhyperpolarization limits the duration of the paroxysmal depolarizing shift; its gradual disappearance is an important factor in the onset of a focal seizure, as discussed later.

Thus it is not surprising that many convulsants act by enhancing excitation or blocking inhibition. Conversely, anticonvulsants act by blocking excitation or enhancing inhibition. For example, the benzodiazepines diazepam (Valium) and lorazepam (Ativan) enhance GABA_A-mediated inhibition and are used in the emergency treatment of prolonged repetitive seizures. The commonly used anticonvulsants phenytoin (Dilantin) and carbamazepine (Tegretol) cause reduction in the opening of the voltage-gated Na⁺ channels that underlie the action potential. The ability of these drugs to block the Na⁺ channels is enhanced by repetitive activity associated with seizures.

The Breakdown of Surround Inhibition Leads to Synchronization

As long as the abnormal electrical activity is restricted to a small group of neurons, there are no clinical manifestations. The synchronization of neurons in the focus is dependent not only on the intrinsic properties of each individual cell but also on the connections between neurons. During the interictal period the abnormal activity is confined to the seizure focus by inhibitory effects of the excited region on surrounding tissue. This *inhibitory surround* is particularly dependent on feed-forward and feedback inhibition by GABA-ergic inhibitory interneurons (Figure 50–9A).

During the development of a focal seizure the inhibitory surround is overcome and the afterhyperpolarization in the neurons of the original focus gradually disappears. As a result, the seizure begins to spread beyond the original focus and a nearly continuous high-frequency train of action potentials is generated (Figure 50–10).

An important factor in the spread of focal seizures appears to be that the intense firing of the pyramidal neurons results in a relative decrease in synaptic transmission from the inhibitory GABAergic interneurons. This decrease may result from a change in the release of GABA (presynaptic mechanisms), a change in the chloride gradient responsible for the GABA_A receptormediated ion flux, or a change in GABA receptor activity (postsynaptic mechanism). Other factors that may contribute to the loss of the inhibitory surround include changes in dendritic morphology, changes in the density of receptors or channels, or changes

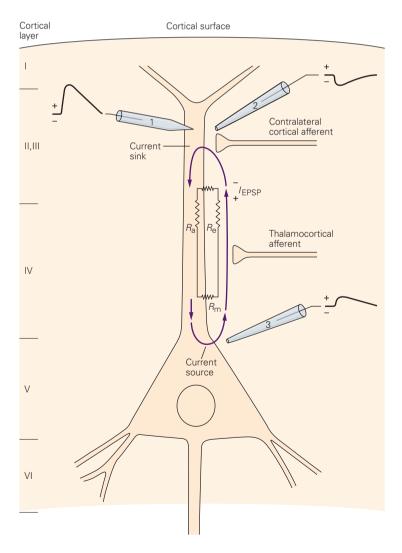

Box 50–1 The Contribution of Individual Neurons to the Electroencephalogram

The contribution of the activity of single neurons to the electroencephalogram (EEG) can be understood by examining a simplified cortical circuit and some basic electrical principles. Pyramidal neurons are the major projection neurons in the cortex (see Chapter 2). The apical dendrites of these cells, which are oriented perpendicular to the cell surface, receive a variety of synaptic inputs. Thus synaptic activity in the pyramidal cells is the principal source of EEG activity.

To understand the contribution of a single neuron to the EEG, consider the flow of charge produced by an excitatory synaptic potential (EPSP) on the apical dendrite of a cortical pyramidal neuron (Figure 50–2). Positive charge enters the dendrite at the site of generation of the EPSP, creating what is commonly called a *current sink*. It then must complete a loop by flowing down the dendrite and back out across the membrane at other sites, creating a current source.

The voltage signal created by a synaptic current is approximately predicted by the Ohm's law (V = IR, where V is voltage, I is current, and R is resistance). Because the resistance of the membrane (R_m) is much

Figure 50-2 The pattern of electrical current flow for an excitatory postsynaptic potential (EPSP) initiated at the apical dendrite of a pyramidal neuron in the cerebral cortex. Activity is detected by three electrodes: an intracellular electrode inserted in the apical dendrite (1), an extracellular electrode positioned near the site of the EPSP in layer II of the cortex (2), and an extracellular electrode near the cell body in layer V (3). At the site of the EPSP (current sink) positive charge flows across the cell membrane (I_{EPSP}) into the cytoplasm, down the dendritic cytoplasm, and then completes the loop by exiting through the membrane near the cell body (current source). The potentials recorded by the extracellular electrodes at the sink and at the source have opposite polarity; the potentials recorded by the intracellular electrode have the same polarity regardless of the site. $R_{\rm m}$, $R_{\rm a}$, and $R_{\rm e}$ are the resistances of the membrane, cytoplasm, and extracellular space, respectively.

larger than that of the salt solution that constitutes the extracellular medium ($R_{\rm e}$), the voltage recorded across the membrane with an intracellular electrode ($V_{\rm m}$) is also larger than the voltage at an extracellular electrode positioned near the current sink ($V_{\rm e}$).

At the site of generation of an EPSP the extracellular electrode detects the voltage change caused by charge flowing away from the electrode into the cytoplasm as a negative voltage deflection. However, an extracellular electrode near the current source records a signal of opposite polarity (compare electrodes 2 and 3 in Figure 50–2). The situation is reversed if the site of the EPSP generation is on the basal segment of the apical dendrites.

In the cerebral cortex excitatory axons from the contralateral hemisphere terminate primarily on dendrites in layers II and III, whereas thalamocortical axons terminate in layer IV (Figure 50–3). As a result, the activity measured by a surface EEG electrode will have opposite polarities for these two inputs even though the basic electrical event, membrane depolarization, is the same.

Similarly, the origin or polarity of cortical synaptic events cannot be unambiguously determined from surface EEG recordings alone. EPSPs in superficial layers and inhibitory postsynaptic potentials (IPSPs) in deeper layers both appear as upward (negative) potentials, whereas EPSPs in deeper layers and IPSPs in superficial layers have downward (positive) potentials (Figure 50–3).

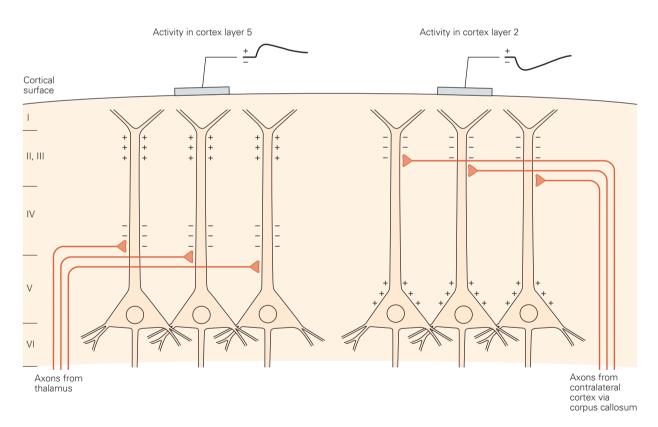

Figure 50–3 Surface electroencephalogram (EEG) recordings do not unambiguously indicate the polarity of synaptic events. The polarity of the surface EEG depends on the location of the synaptic activity within the cortex. A thalamocortical excitatory signal in layer V causes

a upward voltage deflection at the surface EEG electrode because the electrode is nearer the current source. In contrast, an excitatory signal from the contralateral hemisphere in layer II causes an downward deflection because the electrode is nearer the sink.

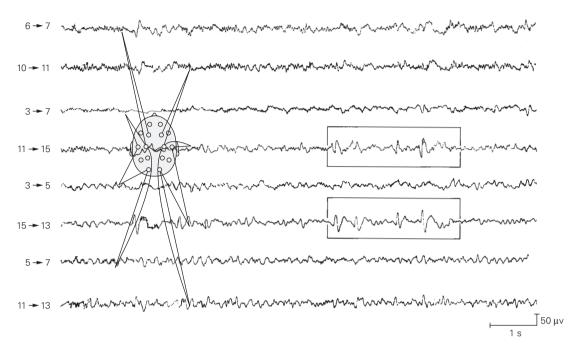

Figure 50–4 The EEG can provide clues to the location of a seizure focus. Each trace represents the electrical activity between pairs of scalp electrodes as indicated in the electrode map. For example, electrode pairs 11–15 and 15–13 measure activity from the right temporal area. In the EEG record shown here, from a patient with epilepsy, sharp waves occur over the right temporal area (records enclosed in boxes). Such

paroxysmal activity arises suddenly and disrupts the normal background EEG pattern. The focal abnormality may indicate that the seizure focus in this patient is in the right temporal lobe. Because the patient had no clinical seizures during the recording, these are interictal spikes (see Figure 50–7). (Adapted, with permission, from Lothman and Collins 1990.)

in the amount of extracellular K^+ ion accumulation. Prolonged firing also transmits action potentials to distant sites in the brain, which in turn may trigger trains of action potentials in neurons that project back to neurons in the seizure focus (backpropagation). Reciprocal connections between the neocortex and thalamus may be particularly important in this regard.

Despite our understanding of such mechanisms, we still do not know what causes a seizure to occur at any particular moment. The inability to predict when a seizure will occur is perhaps the most debilitating aspect of epilepsy. Some patients become adept at adjusting their lifestyle to avoid circumstances that can increase the likelihood of a seizure, such as sleep deprivation or stress. But in many individuals seizures do not follow a predictable pattern. In a few patients sensory stimuli such as flashing lights can trigger seizures, suggesting that repetitive excitation of some circuits causes a change in excitability that is dependent on the frequency of neuronal firing.

Both NMDA-type glutamate receptor activity and GABAergic inhibition undergo changes in sensitivity

that depend on the frequency of firing of the presynaptic neuron, providing a possible cellular mechanism for altered network excitability. On a longer time scale, circadian rhythms and hormonal patterns may also influence the likelihood of seizures, as demonstrated by patients who have seizures only while sleeping (nocturnal epilepsy) or during their menstrual period (catamenial epilepsy). New devices for continuous monitoring at or near a seizure focus may allow clinicians to predict the timing of seizure generation. Such approaches offer the possibility of acute therapeutic intervention such as direct cortical stimulation to prevent seizures. The modest success of implanted vagal nerve stimulators in epilepsy that does not respond to other treatments provides one example of such an approach.

The Spread of Focal Seizures Involves Normal Cortical Circuitry

If activity in the seizure focus is sufficiently intense, the electrical activity begins to spread to other brain regions. Spread of seizure activity from a focus generally

Box 50–2 Mammalian Brain Slice Preparation

The ability to record electrical activity in tissue slices revolutionized the study of the electrophysiological properties of mammalian neurons. Brain slices, which range from 70 to $400~\mu m$ thick, are prepared by quickly removing the brain and immersing it into chilled saline and then sectioning the tissue with a special type of microtome. This technique preserves the basic circuitry of neurons in the slice. The slice is placed in a recording chamber (Figure 50–5) through which oxygenated saline solution is circulated.

There are two principal advantages to recording from neurons in tissue slices. First, more stable electrophysiological recordings can be made because there are no mechanical pulsations resulting from respiration or the pumping of blood. This allows recording from very fine neuronal processes, such as dendrites.

Second, the tissue can be seen under a microscope. When the microscope is equipped with special optics, such as Nomarski differential interference contrast optics, one can actually see unstained living neurons. Direct observation of neurons allows them to be identified from their morphology or by genetic tagging of specific molecules or cell types with green fluorescent protein (Figure 50–6). Direct observation also facilitates patch clamping of individual neurons.

Recording from brain slices has been used to investigate various aspects of the function of mammalian neurons. Through the use of tissue slice techniques, celland molecular-biological approaches can be applied to virtually any part of the mammalian brain. Information obtained from recordings made in brain slices has provided important insights into such problems as synaptic plasticity, the mechanisms of epilepsy, and the actions of drugs on the brain.

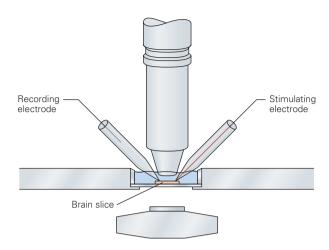

Figure 50–5 Set-up for recording from neurons in a brain slice. The slice is mounted in a chamber attached to the X-Y stage of a microscope. A water-immersion objective allows the slice to be viewed at high power through the saline solution. In this way, separate stimulation and recording electrodes can be placed in the tissue. (Adapted, with permission, from Konnerth 1990.)

В

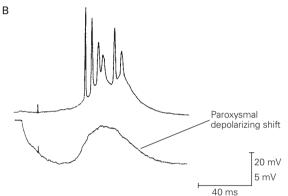

B. A single pyramidal cell has been filled with the fluorescent dye Lucifer yellow through a pipette directed at the cell body. The large apical dendrite projects toward the bottom of the photograph and the basilar dendrites toward the top.

Figure 50–7 Interictal spikes as measured in the EEG result from the synchronized discharges of a group of hippocampal neurons. (Adapted, with permission, from Wong, Miles, and Traub 1984.)

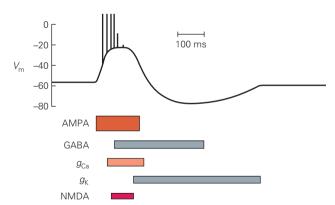

A. Rhythmic firing is evident in an intracellular recording from a pyramidal cell in a hippocampal slice. An extracellular recording from the same slice shows the synchronized discharge of many neurons. This type of synchronized activity underlies interictal spikes in the EEG.

B. The hippocampal slice was perfused with bicuculline, which blocks the inhibition mediated by GABA_A receptors in pyramidal cells and increases the occurrence of seizure-like activity. An intracellular recording from the slice shows several action potentials in one cell (**top trace**). On the next trial (**lower trace**) a hyperpolarizing current was injected to prevent the cell from firing, revealing the large paroxysmal depolarization shift that produces the sudden and long-lasting firing of neurons in a seizure focus.

B Basic cortical circuit

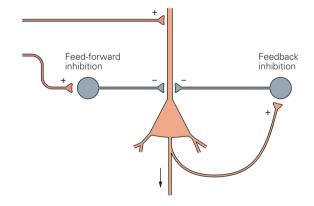

Figure 50–8 The conductances that underlie the paroxysmal depolarizing shift (PDS) of a neuron in a seizure focus.

A. The paroxysmal depolarizing shift is largely dependent on AMPA- and NMDA-type glutamate receptor-channels. The effectiveness of the NMDA-type is enhanced by the opening of voltage-gated ${\rm Ca}^{2+}$ channels $(g_{\rm Ca})$. Following the depolarization the cell is hyperpolarized by activation of GABA receptors (both ionotropic GABA_A and metabotropic GABA_B) as well as by voltage-gated and calcium-activated K⁺ channels $(g_{\rm K})$. (AMPA,

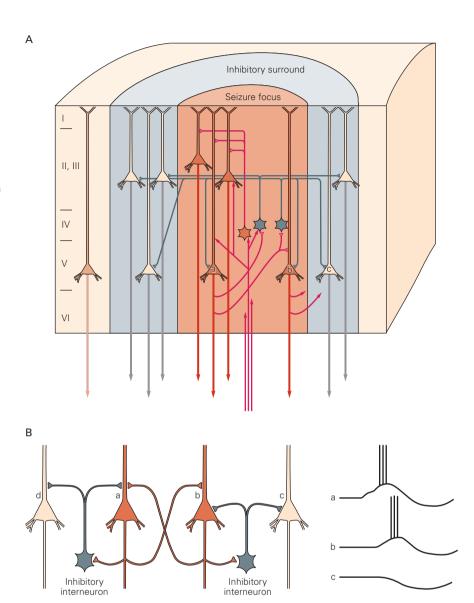

α-amino-3-hydroxy-5-methylisoxazole-4-propionate; **GABA**, γ-aminobutyric acid; **NMDA**, *N*-methyl-p-aspartate.) (Adapted, with permission, from Lothman 1993a.)

B. A simplified version of the inputs to a cortical pyramidal neuron. The **orange** terminals are excitatory, whereas the **gray** terminals are inhibitory. Recurrent axon branches activate inhibitory neurons, causing feedback inhibition of the pyramidal neuron. Extrinsic excitatory inputs can also activate feed-forward inhibition.

Figure 50–9 The spatial and temporal organization of a seizure focus depends on the interplay between excitation and inhibition of neurons in the focus.

A. In this hypothetical seizure focus in the neocortex, the pyramidal cell a shows the typical electrical properties of neurons in a focus (see part B). Activity in cell a activates another pyramidal cell (b), and when many such cells fire synchronously a spike is recorded on the EEG. However, cell a also activates GABAergic inhibitory interneurons (gray). These interneurons can reduce the activity of cells a and b through feedback inhibition, thus limiting the seizure focus temporally, as well as prevent the firing of cells outside the focus, represented here by cell c. This latter phenomenon creates an inhibitory surround that contains the seizure focus spatially. When extrinsic or intrinsic factors alter this balance of excitation and inhibition, the inhibitory surround begins to break down and the seizure activity spreads. (Reproduced, with permission, from Lothman and Collins 1990.)

B. The synaptic connections and activity patterns for cells *a*, *b*, and *c*. Cells *a* and *b* within the seizure focus undergo a paroxysmal depolarizing shift (see Figure 50–7B). However, cell *c* in the region surrounding the seizure focus is hyperpolarized because of input from GABAergic inhibitory interneurons.

follows the same axonal pathways as does normal cortical activity. For example, the neurons in the primary motor and sensory cortex are organized functionally into vertical columns that run from the pial surface to the underlying white matter (see Chapter 15). The major input to sensory cortex comes from the thalamus and terminates in layer IV, whereas the output cells are in layer V. Reciprocal thalamocortical pathways connect the thalamus and cortex. Intracortical connections occur via short U fibers between adjacent sulci and via the corpus callosum, the major connection between the cerebral hemispheres. These thalamocortical, subcortical, and interhemispheric pathways can all become involved in seizure spread.

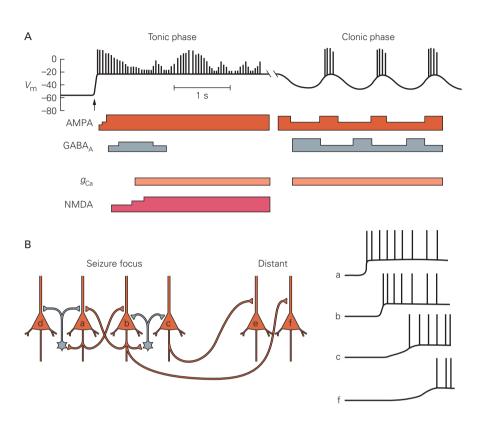

Focal seizure activity can spread from the seizure focus to other areas of the same hemisphere or across the corpus callosum to the contralateral hemisphere (Figure 50–11A). Once both hemispheres become involved, the seizure has become secondarily generalized. At this point the patient generally experiences loss of consciousness. The spread of a focal seizure usually occurs within a few seconds but can also take many minutes.

As the focal seizure begins to spread, the patient may experience some warning symptoms (an aura). If the seizure spreads slowly across the cortex, it may lead to a progression of clinical symptoms—a Jacksonian march in the case of a focal seizure involving the motor cortex.

Figure 50–10 A focal seizure begins with the loss of the afterhyperpolarization and surround inhibition. (Adapted, with permission, from Lothman 1993a.)

A. At the onset of a seizure (arrow) neurons in the seizure focus depolarize as in the first phase of a paroxysmal depolarizing shift. However, unlike the interictal period, the depolarization persists for seconds or minutes. The GABA-mediated inhibition fails, whereas excitatory activity in the AMPA- and NMDA-type glutamate receptors is functionally enhanced. This activity corresponds to the tonic phase of a secondarily generalized tonic-clonic seizure. As the GABA-mediated inhibition gradually returns, the neurons in the seizure focus enter the clonic phase, a period of oscillation.

B. As the surround inhibition mediated by GABAergic interneurons breaks down, neurons in the seizure focus become synchronously excited and send trains of action potentials to distant neurons, thus spreading the abnormal activity from the focus. Compare the pattern of activity in cells *a* to *c* here with that during the interictal period in Figure 50–9B.

Focal seizures that quickly undergo secondary generalization provide little or no warning. Rapid secondary generalization is more likely if the seizure begins in the neocortex than if it begins in the limbic system (in particular, the hippocampus and amygdala).

An interesting unanswered question is what terminates a seizure. The only definitive conclusion at this point is that termination is not caused by metabolic exhaustion. During the initial 30 seconds or so of a typical secondarily generalized tonic-clonic seizure, neurons in the involved areas undergo prolonged depolarization and continuously fire action potentials (caused by loss of the afterhyperpolarization that normally follows a paroxysmal depolarizing shift). As the seizure evolves, the neurons begin to repolarize and the afterhyperpolarization reappears. The cycles of depolarization and repolarization correspond to the clonic phase of the seizure (Figure 50–10A).

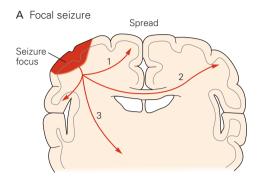

The seizure is often followed by a period of decreased electrical activity, the postictal period, that may be accompanied by confusion, drowsiness, or even focal neurological deficits such as a hemiparesis (Todd paralysis). A neurological exam in the postictal

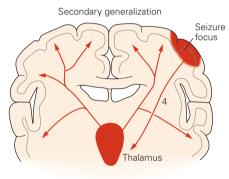

period can lead to insights about the locus of the seizure focus.

Primary Generalized Seizures Are Driven by Thalamocortical Circuits

Unlike the focal seizure a primary generalized seizure disrupts normal brain activity in both cerebral hemispheres simultaneously (Figure 50–11B). Generalized seizures and their associated epilepsies vary both in their manifestations and etiologies. Although the cellular mechanisms of primary generalized seizures differ in a number of interesting respects from those of focal or secondarily generalized focal seizures, a primary generalized seizure can be difficult to distinguish from a focal seizure that rapidly generalizes.

The most studied type of primary generalized seizure is the typical absence seizure (petit mal), whose characteristic EEG pattern (the 3 Hz spike-wave pattern in Figure 50–12A) was first identified by Hans Berger in 1933. F.A. Gibbs recognized the relationship

B Primary generalized seizure

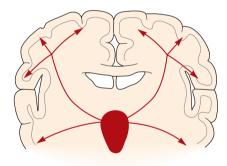

Figure 50–11 Seizures propagate via several pathways. (Reproduced, with permission, from Lothman 1993b.)

A. Focal seizures can spread locally from a focus via intrahemispheric fibers (1) and more remotely to homotopic contralateral cortex (2) and subcortical centers (3). The secondary generalization of focal seizure activity spreads to subcortical centers via projections to the thalamus (4). Widespread thalamocortical interconnections then contribute to rapid activation of both hemispheres.

B. Primary generalized seizures, such as a typical absence seizure, spread primarily through interconnections between the thalamus and cortex.

of this EEG pattern to typical absence seizures (he aptly described the pattern as "dart and dome") and he attributed the mechanism to generalized cortical disturbance. The distinctive clinical features of typical absence seizures are clearly correlated with the EEG activity.

The typical absence seizure begins suddenly, lasts 10 to 30 seconds, and produces loss of awareness and only minor motor manifestations such as blinking or lip smacking. Unlike secondarily generalized seizures, primary generalized seizures are not preceded by an aura or followed by postictal symptoms. The spikewave EEG pattern can be seen in all cerebral areas simultaneously and is immediately preceded and followed by normal background activity. Brief (1–5 s) runs of 3 Hz EEG activity without apparent clinical symptoms are common in patients with childhood absence seizures.

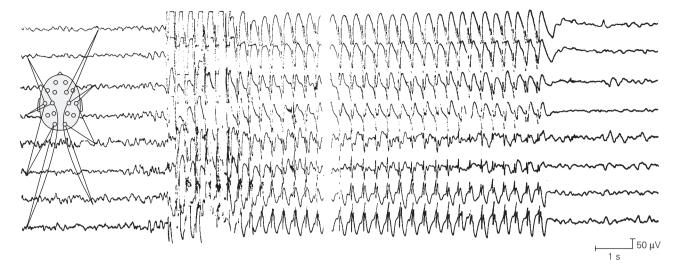

In contrast to Gibbs's hypothesis of diffuse cortical hyperexcitability, Penfield and Jasper noted that the EEG in typical absence seizures is similar to rhythmic EEG activity in sleep, so-called sleep spindles (see Figure 51–1). They proposed a "centrencephalic" hypothesis in which rapid generalization was attributed to rhythmic activity (pacing) by neuronal aggregates in the upper brain stem or thalamus that project diffusely to the cortex.

Research on animal models of generalized seizures and recent studies on the genetics of generalized epilepsy suggest that elements of both hypotheses are correct. In cats parenteral injections of penicillin, a weak GABA_A antagonist, produce behavioral unresponsiveness associated with an EEG pattern of bilateral synchronous slow waves (generalized penicillin epilepsy). During such a seizure thalamic and cortical cells become synchronized through the same reciprocal thalamocortical connections that contribute to normal sleep spindles during slow wave sleep.

Such seizures could in theory represent a form of diffuse hyperexcitability in the cortex. Recordings from individual cortical neurons show an increase in the rate of firing during a depolarizing burst that in turn produces a powerful GABAergic inhibitory feedback that hyperpolarizes the cell for approximately 200 ms after each burst (Figure 50–12C). This depolarization followed by inhibition differs fundamentally from the paroxysmal depolarizing shift in focal seizures in that GABAergic inhibition is preserved. In the typical absence seizure the summated activity of the bursts produces the spike while the summated inhibition produces the wave of the spike-wave EEG pattern.

What are the properties of cells and networks that facilitate this generalized and synchronous activity?

A Spike and wave activity in typical absence seizure

B Thalamocortical projections

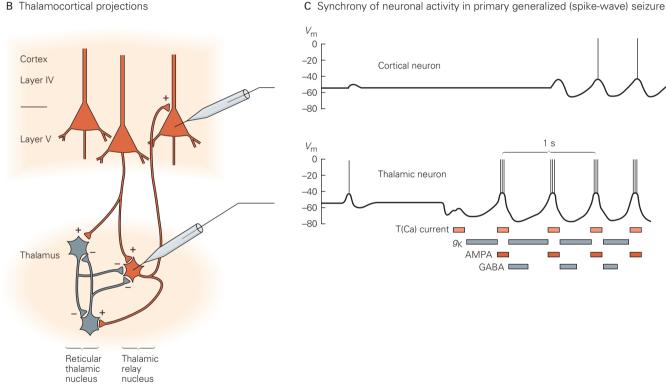

Figure 50-12 The generation of primary generalized seizures.

A. This EEG from a 12-year-old patient with typical absence (petit mal) seizures shows the sudden onset of synchronous spikes at a frequency of 3 per second and wave activity lasting approximately 14 seconds. The seizure was clinically manifest as a staring spell with occasional eye blinks. Unlike a focal seizure there is no buildup of activity preceding the seizure and the electrical activity returns abruptly to the normal background level following the seizure. Discontinuity in the trace is the result of removal of a 3 second period of recording. (Reproduced, with permission, from Lothman and Collins 1990.)

B. The thalamocortical connections that participate in the generation of sleep spindles (see Chapter 51) are thought to be essential for the generation of primary generalized seizures. Pyramidal cells in the cortex are reciprocally connected by excitatory synapses with thalamic relay neurons. GABAergic interneurons in the reticular thalamic nucleus are excited by pyramidal cells in the cortex and thalamic relay neurons, and inhibit the thalamic relay cells. The interneurons are also reciprocally connected.

C. Neuronal activity of cortical and thalamic neurons becomes synchronized during a primary generalized seizure. The depolarization is dependent on conductances in AMPA-type glutamate receptor-channels and T-type voltage-gated Ca²⁺ channels. The repolarization is caused by GABA-mediated inhibition as well as voltage- and calcium-dependent K^+ conductances (g_k) . (Reproduced, with permission, from Lothman 1993a.)

An early clue came from studies of the intrinsic bursting of thalamic relay neurons. Henrik Jahnsen and Rodolfo Llinas found that these neurons robustly express the T-type voltage-gated Ca²⁺ channel that is inactivated at the resting membrane potential but becomes available for activation when the cell is hyperpolarized. A subsequent depolarization then transiently opens the Ca²⁺ channel (thus the name T-type) and the Ca²⁺ influx generates low-threshold Ca2+ spikes. Consistent with the hypothesis that T-type channels contribute to absence seizures, certain anticonvulsant agents that block absence seizures, such as ethosuximide (Zarontin) and valproic acid (Depakote), also block T-type channels. T-type channels are encoded by three related genes (Cav3.1-Cav3.3), with Cav3.1 the predominant type in the thalamus.

The circuitry of the thalamus seems ideally suited to the generation of primary generalized seizures. The pattern of thalamic neuron activity during sleep spindles suggests a reciprocal interaction between thalamic relay neurons and GABAergic interneurons in the thalamic reticular nucleus and perigeniculate nucleus (Figure 50-12B). Studies of thalamic brain slices by David McCormick and his colleagues indicate that the interneurons hyperpolarize the relay neurons, thus removing the inactivation of T-type Ca²⁺ channels. This action leads to an oscillatory response: T-type Ca²⁺ channels drive rebound firing in the relay neurons, which stimulates GABAergic interneurons and leads to another round of rebound firing. The relay neurons also excite cortical neurons, as manifested in the EEG by a spindle wave (see Chapter 51). Both the T-type Ca²⁺ channel and the GABA_B receptor-channel play an important role in the generation of this activity that resembles human absence seizures.

Mutations in voltage-gated Ca²⁺ channels have produced several mouse models of generalized epilepsy, including the so-called *totterer* mouse. Studies of these mutants by Jeffrey Noebels and his colleagues have revealed that the animals develop primary generalized seizures when they reach adolescence. EEGs in these animals show a paroxysmal spike-wave discharge and seizures that are characterized by an arrest of behavior, similar to typical absence seizures.

Locating the Seizure Focus Is Critical to the Surgical Treatment of Epilepsy

The pioneering studies of the surgeon Wilder Penfield in Montreal in the early 1950s led to the recognition that removal of the temporal lobe in certain patients with focal seizures of hippocampal origin could reduce or cure epilepsy. As surgical treatment for difficult-tocontrol (so-called intractable) focal seizures became more common, it became clear that the surgical outcome is directly related to the adequacy of the resection. Thus precise localization of the seizure focus is essential.

Electrical mapping of seizure foci originally relied on the surface EEG, which we have seen is biased toward particular sets of neurons in the cortex immediately adjacent to the skull. However, intractable seizures often begin in deep structures that show little or no abnormality on the surface EEG at the onset of the seizure. Thus the surface EEG is somewhat limited in identifying the location of the seizure focus.

The development of magnetic resonance imaging (MRI) has markedly improved the noninvasive anatomical mapping of seizure foci. This technique is now routine in the evaluation of seizure foci in the temporal lobe and increasingly promising for identifying seizure foci in other locations. Anatomical mapping of seizure foci by MRI has shown that most patients with intractable temporal lobe seizures have atrophy and cell loss in the mesial portions of the hippocampal formation. There is a dramatic loss of neurons within the hippocampus (mesial temporal sclerosis), changes in dendritic morphology of surviving cells, and collateral sprouting of some axons. The anatomical resolution of MRI provides a noninvasive, quantitative assessment of the size of the hippocampus in epilepsy patients. Loss of volume of the hippocampus on one or another side of the brain generally correlates well with the localization of seizure foci in the hippocampus by electrical criteria.

Patients with mesial temporal lobe epilepsy often have unilateral disease, which leads to shrinkage of the hippocampus on one side. This is apparent in brain imaging as an apparent dilatation of the temporal horn of the lateral ventricle (Box 50–3). However, in many patients abnormalities cannot be detected using anatomical MRI; thus several functional imaging methods have been used as well.

Metabolic mapping takes advantage of the changes in cerebral metabolism and blood flow that occur in the seizure focus during the ictal and interictal periods. The electrical activity associated with a seizure places a large metabolic demand on brain tissue. During a focal seizure there is an approximately threefold increase in glucose and oxygen use. Between seizures the seizure focus often shows decreased metabolism. Despite the increased metabolic demands, the brain is able to maintain normal adenosine triphosphate (ATP) levels during a focal seizure. Conversely, the transient interruption of breathing during a generalized

Box 50–3 Surgical Treatment of Temporal Lobe Epilepsy

A 27-year-old woman had episodes of decreased responsiveness beginning at age 19 years. At first she would stare off and appear confused during the episodes. Later she developed an aura consisting of a feeling of fear. This fear was followed by altered consciousness, a wide-eyed stare, tightening of the left arm, and a scream that lasted for 14 to 20 seconds (Figure 50–13).

These spells were diagnosed as complex partial seizures. The seizures occurred several times a week despite treatment with several antiepileptic drugs. She was unable to work or drive because of frequent seizures. She had a history of meningitis at age 6 months, and throughout childhood she had experienced brief episodes of altered perception described as "like someone threw a switch."

Based on an evaluation summarized in Figures 50–14 and 50–15, the right amygdala and hippocampus (amygdalohippocampectomy) were resected. The patient was seizure-free following the operation and returned to full-time employment.

Figure 50–13 The patient is shown reading quietly in the period preceding the seizure (A), during the period when she reported a feeling of fear (B), and during the period

when there was alteration of consciousness and an audible scream (C). (Reproduced, with permission, from Dr. Martin Salinsky.)

convulsive seizure causes a decrease in oxygen levels in the blood. This results in a drop in ATP concentration and an increase in anaerobic metabolism as indicated by rising lactate levels. This oxygen debt is quickly replenished in the postictal period, and no permanent damage to brain tissue results from a single generalized seizure.

Positron emission tomography (PET) scans of patients with focal seizures originating in the mesial temporal lobe frequently show interictal hypometabolism, with metabolic changes extending to the lateral temporal lobe, ipsilateral thalamus, basal ganglia, and frontal cortex. PET scans using nonhydrolyzable glucose analogs have been particularly helpful in identifying seizure foci in patients with normal MRI scans and in some early childhood epilepsies.

Unfortunately, for unclear reasons PET has been less reliable in localizing seizure foci in extratemporal areas such as the frontal lobe. An additional limitation is the expense of the PET scan and the short half-life of the isotopes (a nearby cyclotron is required). PET scanning can also be used to look for functional changes

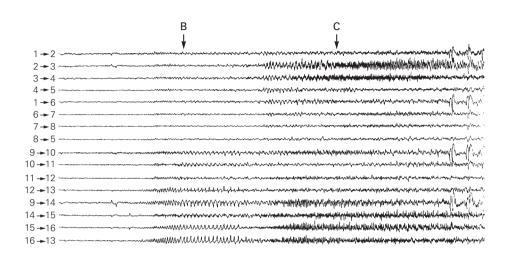

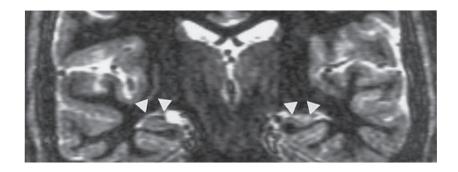

Figure 50–14 The EEG at the time of the photographs in Figure 50–13. Low-amplitude background rhythms occur at the beginning (left). At the point when the patient reported fear (B), there is a buildup of EEG activity at the onset of a complex partial seizure, but this activity is confined to the EEG electrodes over the right hemisphere

(electrodes 9–16). At the point consciousness is altered (C) the seizure activity has spread to the left hemisphere (electrodes 1–8). EEG spike-waves are particularly prominent in leads 9–10 and 9–14 over the right anterior temporal region. (Reproduced, with permission, from Dr. Martin Salinsky.)

Figure 50–15 Enhanced MRI reveals atrophy of the right hippocampus (arrowheads on right) and a normal left hippocampus (arrowheads on left). (Reproduced, with permission, from Dr. Martin Salinsky.)

in neurotransmitter receptor binding and transport related to seizure activity.

A related technique that measures cerebral blood flow, single photon emission computed tomography (SPECT), has been used more frequently than PET. SPECT does not have the resolution of PET but can be performed in the nuclear medicine department of many large hospitals. Injection of radioisotopes and SPECT imaging at the time of a seizure (ictal SPECT) reveals a pattern of hypermetabolism followed by hypometabolism in the seizure focus and surrounding

tissue. The use of magnetoencephalography and functional MRI may offer further advantages in the mapping of seizure foci.

With rigorous selection of patients for epilepsy surgery, the cure rate for seizures originating in the temporal lobe can approach 80%. Patients with complicating factors (eg, multiple foci) have lower success rates. However, even among these patients the number or severity of seizures is reduced. Patients who have been *cured* of seizures still experience cognitive problems such as memory loss and social problems such as

adjustments to more independent living and limited employment opportunities. These factors emphasize the need for treatment as early in life as feasible.

Prolonged Seizures Can Cause Brain Damage

Repeated Convulsive Seizures Are a Medical Emergency

As noted earlier, brain tissue can compensate for the metabolic stress of a focal seizure or the transient decrease in oxygen delivery during a single generalized seizure. In a generalized seizure, stimulation of the hypothalamus leads to massive activation of the stress response of the sympathetic nervous system. The increased systemic blood pressure and serum glucose initially compensate for increased metabolic demand, but these homeostatic mechanisms fail during prolonged seizures, particularly seizures that are convulsive. The resulting systemic metabolic derangements, including hypoxia, hypotension, hypoglycemia, and acidemia, lead to a reduction in high-energy phosphates (ATP and phosphocreatine) in the brain and thus can be devastating to brain tissue.

Systemic complications such as cardiac arrhythmias, pulmonary edema, hyperthermia, and muscle breakdown can also occur. Repeated generalized seizures without return to full consciousness between seizures, called *status epilepticus*, is a true medical emergency. This condition requires aggressive seizure management and general medical support because 30 or more minutes of continuous convulsive seizures leads to brain injury or even death. Status epilepticus can involve nonconvulsive seizures (focal or primary generalized) for which the metabolic consequences are much less severe.

Excitotoxicity Underlies Seizure-Related Brain Damage

Repeated seizures can damage the brain independently of cardiopulmonary or systemic metabolic changes, suggesting that local factors in the brain can result in neuronal death. The immature brain appears particularly vulnerable to such damage, perhaps because of greater electrotonic coupling between neurons in the developing brain, less effective potassium buffering by immature glia, and decreased glucose transport across the blood-brain barrier.

Wilhelm Sommer in 1880 first noted the vulnerability of the hippocampus to such insults, with preferential loss of the pyramidal neurons in the CA1 and CA3 regions. This pattern has been duplicated in experimental animals by electrical stimulation of afferents to the hippocampus or by injection of excitatory amino acid analogs such as kainic acid. Interestingly, kainic acid causes local damage at the site of injection and also at the site of termination of afferents originating at the injection site.

These observations indicate that release of the excitatory transmitter L-glutamate during excessive stimulation such as a seizure can itself cause neuronal damage, a condition that has been termed *excitotoxicity*. Excitotoxicity following seizures probably is caused more by excessive stimulation of synaptically-activated glutamate receptors than by tonic increases in extracellular glutamate. The histological appearance of acute excitotoxicity includes massive swelling of cell bodies and dendrites, which is consistent with the predominant locations of glutamate receptors and excitatory synapses.

Although the cellular and molecular mechanisms of excitotoxicity are still not fully understood, several features are clear. Overactivation of glutamate receptors leads to an excessive increase in intracellular Ca²⁺ that can activate a self-destructive cellular cascade involving many calcium-dependent enzymes, such as phosphatases, proteases, and lipases. Lipid peroxidation can also cause production of free radicals that damage vital cellular proteins and lead to cell death. The role of mitochondria in Ca²⁺ homeostasis and in control of free radicals may also be important. The pattern of cell death was first thought to reflect necrosis because of the autolysis of critical cellular proteins. However, *death genes*, characteristic of programmed cell death or apoptosis, may also be involved.

Seizure-related brain damage or excitotoxicity can be specific to certain types of cells in particular brain regions, perhaps because of protective factors, such as calcium-binding proteins in some cells, and sensitizing factors, such as the expression of calcium-permeable glutamate receptors in other cells. For example, excitotoxicity induced in vitro by activation of AMPA-type glutamate receptors preferentially affects interneurons that express AMPA-type receptors that have high Ca²⁺ permeability, providing a possible mechanism for their selective vulnerability.

Several outbreaks of *amnestic* shellfish poisoning provide a vivid example of the consequences of overactivation of glutamate receptors. Domoic acid, a glutamate analog not present in the brain, is a natural product of certain species of marine algae that flourish during appropriate ocean conditions. Domoic acid can be concentrated by filter feeders such as shellfish. Ingestion of domoic acid contaminated shellfish sporadically causes outbreaks of neurological damage, including severe seizures and memory loss (amnesia). The area most sensitive to damage is the hippocampus, providing further support for the excitotoxicity hypothesis and the critical

role of the hippocampus in learning and memory (see Chapter 65).

The Factors Leading to Development of Epilepsy Are an Unfolding Mystery

A single seizure does not warrant a diagnosis of epilepsy. Normal people can have a seizure under extenuating circumstances, such as following drug ingestion or extreme sleep deprivation. Clinicians look for possible causes of seizures in such cases but usually do not begin treatment with anticonvulsants following a single seizure. Unfortunately, our understanding of what factors contribute to susceptibility to epilepsy is still rudimentary.

Some forms of epilepsy are caused in part by a genetic predisposition. For example, infants with febrile seizures often have a family history of similar seizures. The role of genetics in epilepsy is supported by the existence of familial epileptic syndromes in humans as well as seizure-prone animal models with such exotic names as *Papio papio* (a baboon with photosensitive seizures), audiogenic mice (in which loud sounds induce seizures), and *reeler* and *totterer* mice (names alluding to the clinical manifestations of cerebellar mutations in these animals). Even with a genetic predisposition or a structural lesion, the evolution of the epileptic phenotype often involves maladaptive changes in brain structure and function.

Among the Genetic Causes of Epilepsy Are Ion Channel Mutations

Recent studies have provided a wealth of new information concerning the molecular genetics of epilepsy. At present more than 70 genes have been linked to an epileptic phenotype; approximately half of these were discovered in humans and the others in animals, mostly mice. The affected proteins include ion channel subunits, proteins involved in synaptic transmission such as transporters, vesicle proteins, synaptic receptors, and molecules involved in Ca²⁺ signaling. For example, seizures in the totterer mutant mouse are due to a spontaneous mutation in the gene that encodes the Ca_V2.1subunit or α_{1A} -subunit of the P/Q-type voltage-gated Ca²⁺ channel. That mutations in these classes of proteins can cause epilepsy is perhaps not unexpected given the dependence of seizures on synaptic transmission and neuronal excitability. Some of the other genes linked to epilepsy in mice have been more surprising, such as the genes for Centromere BP-B, a DNA-binding protein, and the sodium/hydrogen exchanger, which is affected in the slow-wave epilepsy mouse.

A wide variety of human gene mutations cause neurological disorders of which epilepsy is only one manifestation. For example, Rett syndrome, a disease associated with mental retardation, autism, and seizures, is caused by mutations in the gene that codes for MECP2 (methyl-CpG-binding protein-2), a regulator of gene transcription. Although the exact links are unknown, it is clear that mutations in many different genes may result in epilepsy.

Most genetic epilepsy syndromes in humans have complex rather than simple (Mendelian) inheritance patterns, suggesting the involvement of many rather than single genes. Nevertheless, a number of *monogenic* epilepsies have been identified in studies of families with epilepsy. Ortrud Steinlein and colleagues reported in 1995 that a mutation in the α_4 -subunit of the nicotinic acetylcholine receptor-channel is responsible for autosomal dominant nocturnal frontal lobe epilepsy (ADN-FLE), the first example of an autosomal gene defect in human epilepsy. Since then other voltage- and ligandgated channel proteins have been identified as critical genes for epilepsy. Mutations in ion channel genes (channelopathies) constitute a major cause of known monogenic epilepsies (Figure 50–16).

In voltage-gated channels, mutations largely affect the main pore-forming subunit(s), but there are also examples of epilepsy-causing mutations in regulatory subunits. When examined in vitro, the mutant channel proteins are most commonly associated with either reductions in the expression of the channel on the surface of the plasma membrane (caused by reduced targeting to the membrane or premature degradation) or altered kinetics of the channels. The problem of how changes in ion channel gating might affect the excitability of neurons and their synchronization during seizure generation is straight-forward. However, mutations in ion channel genes may also affect neuronal development and thus exert their epileptogenic effects through a secondary action on cell migration, network formation, or patterns of gene expression.

In the early days of research on epilepsy genes it was widely expected that the genes would underlie generalized epilepsies, based on the idea that a gene mutation (eg, in an ion channel) would be expected to affect most neurons. However, the first autosomal dominant epilepsy gene discovered by Steinlein and colleagues causes focal seizures. In retrospect this should not be so surprising because channel subunits are rarely expressed uniformly in the brain, and some brain regions are more likely to generate seizures than other regions. For example, *totterer* mice with mutations in the pore-forming Ca_v2.1-subunit of P/Q-type Ca²⁺ channels show spike-wave type seizures. The seizures occur principally in immature mice, presumably

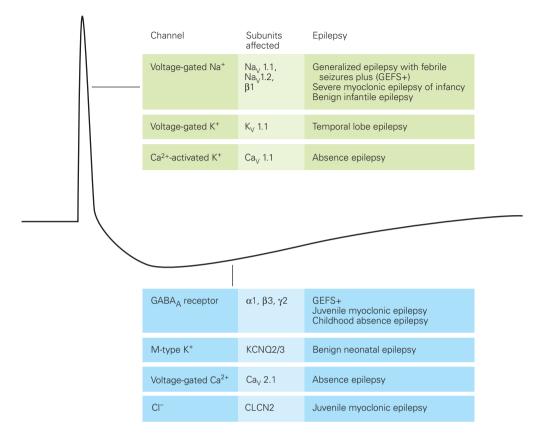

Figure 50–16 Gene mutations that affect ion channel function are a major cause of monogenic human epilepsies. The human epilepsy genes discovered in the past 10 years can affect multiple phases of neuronal excitability, from the shape of the action potential to the afterpotentials and synaptic events

that follow. In the figure the mutations listed near the spike affect the repolarization of the action potential; those listed below affect either the afterhyperpolarization, synaptic conductances, or interspike interval. (Adapted, with permission, from Jeffrey Noebels, unpublished data.)

because P/Q-type Ca²⁺ channels are the predominant isoform early in development, whereas N-type Ca²⁺ channels predominate later.

Moreover, one mutant gene can give rise to different epilepsy phenotypes, whereas different mutant genes can cause the same epilepsy phenotype. As an example of the latter, the ADNFLE syndrome, first discovered as a mutation in the α_4 -subunit of the nicotinic acetylcholine receptor, can also be caused by a mutation in the α_2 -subunit. But not all family members who carry this autosomal dominant mutation have epilepsy, indicating that even in monogenic epilepsy other, perhaps nongenetic, factors can influence the phenotype.

The GEFS+ syndrome (generalized epilepsy with febrile seizures plus) is a good example of this heterogeneity. It can involve different seizure types in different family members and has been seen in families with mutations in the genes for three different Na⁺ channel subunits and two GABA_A receptors. Family studies of primary generalized epilepsy suggest that seizure

types may be heritable within families. These issues indicate that monogenic epilepsies are likely modified by other genes, environmental influences, and even experience-dependent changes in synapses.

Altered cortical development may be a common cause of epilepsy. The higher resolution of MRI scans has revealed an unexpectedly large number of cortical malformations and localized areas of abnormal cortical folding in patients with epilepsy. Thus mutations that disturb the normal formation of the cortex or network wiring are candidate genes for epilepsy. This idea is supported by the mapping of two X-linked cortical malformations with epileptic phenotypes: familial periventricular heterotopia and familial subcortical band heterotopia. The genes responsible for these two disorders, filamin A and doublecortin, are presumably important in neuronal migration. Small focal cortical dysplasias can function as seizure foci that give rise to focal and secondarily generalized seizures, whereas more extensive cortical malformations can cause a

variety of seizure types and usually are associated with other neurological problems.

Unfortunately, most cases of epilepsy cannot be explained by even the recent surge in the identification of epilepsy genes. The identification of large numbers of patients through online registries, such as the Epilepsy Phenome/Genome Project, may provide the population sample needed to evaluate susceptibility genes that underlie complex inheritance patterns.

Epilepsies Involving Focal Seizures May Be a Maladaptive Response to Injury

Epilepsies involving repeated focal seizures often develop following a discrete cortical injury such as a penetrating head wound. This injury serves as the nidus for a seizure focus, leading at some later point to seizures. This has led to the idea that the early insult triggers a set of progressive physiological or anatomical changes that lead to chronic seizures. That is, the characteristic *silent* interval (usually months or years) between the insult and the onset of recurrent seizures may be a period of maladaptive changes that might be amenable to therapeutic manipulation. Although

an attractive hypothesis, a unified picture of this process has yet to emerge. The most promising evidence has come from studies of tissue removed from patients undergoing temporal lobectomy and rodent models of limbic seizures.

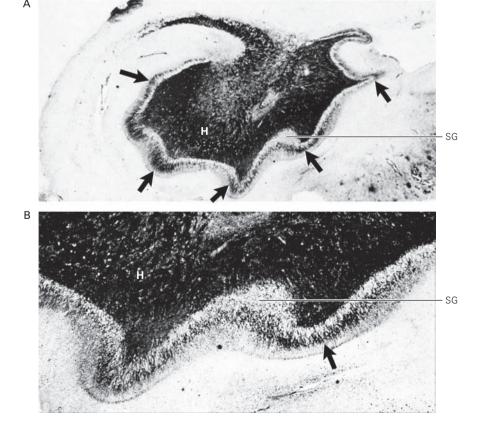

In one experimental model hyperexcitability is induced by repeated stimulation of limbic structures, such as the amygdala or hippocampus. The initial stimulus is followed by an electrical response (the afterdischarge) that becomes more extensive and prolonged with repeated stimuli until a generalized seizure occurs. This process, called *kindling*, can be induced by electrical or chemical stimuli. Many investigators believe that kindling may contribute to the development of epilepsy in humans.

Kindling is thought to involve synaptic changes that resemble those important in learning and memory (see Chapter 65). These include short-term changes in excitability and persistent morphological changes, including axonal sprouting. Rearrangements of synaptic connections have been observed in the dentate gyrus of patients with long-standing focal seizures of hippocampal origin as well as following kindling in experimental animals (Figure 50–17). In addition

Figure 50–17 Mossy fiber synaptic reorganization (sprouting) in the human temporal lobe may cause hyperexcitability. (Reproduced, with permission, from Sutula et al. 1989.)

A. Timm stain of a transverse section of hippocampus removed from a patient at the time the temporal lobe was resected to control epilepsy. The stain appears black in the axons of the dentate granule cells (mossy fibers) because of the presence of zinc in these axons. The mossy fibers normally pass through the dentate hilus (H) on their way to synapse on CA3 pyramidal cells. In the epileptic tissue shown here stained fibers appear in the supragranular layer of the dentate gyrus (SG), which now contains not only the granule cell dendrites but also newly sprouted mossy fibers. These aberrant sprouts form new recurrent excitatory synapses on dentate granule cells.

B. This high magnification of a segment of the supragranular layer shows the Timm-stained mossy fibers in greater detail.

to axonal sprouting, changes include alterations in dendritic structure, control of transmitter release, and expression of ion channels and pumps.

The long-term changes that lead to epilepsy also are likely to involve specific patterns of gene expression. For example, the proto-oncogene c-fos and other immediate early genes as well as growth factors can be activated by seizures. Because many immediate early genes encode transcription factors that control other genes, the gene products that result from epileptiform activity could initiate a cascade of changes that contribute to the development of epilepsy by altering such mechanisms as cell fate, axon targeting, dendritic outgrowth, and synapse formation.

An Overall View

Seizures are one of the most dramatic examples of the collective electrical behavior of the mammalian brain. The distinctive clinical patterns of focal seizures and primary generalized seizures can be attributed to the different patterns of activity of cortical neurons. Studies of focal seizures in animals reveal a series of events—from the activity of neurons in the seizure focus to synchronization and subsequent spread of epileptiform activity throughout the cortex. The gradual loss of GABAergic surround inhibition is critical to the early steps in this progression. In contrast, generalized seizures are thought to arise from activity in thalamocortical circuits, perhaps combined with a general abnormality in the membrane excitability of cortical neurons.

The EEG has long provided a window on the electrical activity of the cortex, both in normal phases of arousal and during abnormal activities such as seizures. The EEG can be used to identify certain electrical activity patterns associated with seizures, but it provides limited insight into the pathophysiology of seizures. Several much more powerful and noninvasive approaches are now available to locate a seizure focus. These advances have led to the widespread and successful use of epilepsy surgery for selected patients, particularly those with focal seizures that originate in the hippocampus.

The increasing power of genetic, molecular, and modern cell-physiological techniques applied to the study of seizures and epilepsy gives new hope that this research will provide new therapeutic options for patients afflicted with epilepsy as well as new insights into the function of the mammalian brain. Further neurobiological studies of the progression from an acute seizure to the development of epilepsy should provide

alternative strategies for treatment beyond the standard options of anticonvulsants or epilepsy surgery.

Sleep and Dreaming

Sleep Consists of Alternating REM and Non-REM Periods

Non-REM Sleep Has Four Stages

REM and Non-REM Dreams Are Different

Sleep Obeys Circadian and Ultradian Rhythms

The Circadian Rhythm Clock Is Based on a Cyclic Production of Nuclear Transcription Factors

The Ultradian Rhythm of Sleep Is Controlled by the Brain Stem

Sleep-Related Activity in the EEG Is Generated Through Local and Long-Range Circuits

Sleep Changes with Age

The Characteristics of Sleep Vary Greatly Between Species Sleep Disorders Have Behavioral, Psychological, and Neurological Causes

Insomnia Is the Most Common Form of Sleep Disruption

Excessive Daytime Sleepiness Is Indicative of Disrupted Sleep

The Disruption of Breathing During Sleep Apnea Results in Fragmentation of Sleep

Narcolepsy Is Characterized by Abnormal Activation of Sleep Mechanisms

Restless Leg Syndrome and Periodic Leg Movements Disrupt Sleep

Parasomnias Include Sleep Walking, Sleep Talking, and Night Terrors

Circadian Rhythm Sleep Disorders Are Characterized by an Activity Cycle That Is Out of Phase with the World

An Overall View

LEEP IS A REMARKABLE STATE. It consumes fully a third of our lives—approximately 25 years in the average lifetime—yet most of us know little about this daily excursion into our inner world. Perhaps even more surprising, we are still hard pressed to give a *raison d'etre* for sleep.

The exact functions of sleep and of dreaming, one of the more spectacular components of sleep, have been debated over the ages and are still not known. Do dreams reveal some inner psychological functioning of unconscious mental processes, as Sigmund Freud first suggested, or are they merely the consequence of random firing of neurons in the brain? The psychic content of dreams has been a rich subject of speculation throughout history. Plato, anticipating Sigmund Freud, thought that all of us have a "terrible, fierce, and lawless blood of desires, which it seems are revealed in our sleep," whereas Aristotle believed that dreams are merely afterthoughts of the day's activities and experiences.

Although we have only limited understanding of the functions of sleep, our insight into its mechanisms has increased greatly over the past 50 years. We have moved away from the intuitively appealing but incorrect notion that sleep is a period of relative inactivity and rest—one that occurs reflexively in response to reduction of sensory input—to the current view that sleep is a highly organized state generated by the cooperative interplay of many behavioral and neural components. Although in many respects the biological function of sleep remains a mystery, we have begun to understand the cellular and molecular processes underlying sleep.

Sleep Consists of Alternating REM and Non-REM Periods

Sleep affects all of our bodily and mental functions, from the regulation of hormonal levels to muscle tone, from the regulation of respiration rate to the content of our thought processes. Given these important behavioral changes, it is not surprising that the brain's overall electrical activity changes significantly with sleep. During wakefulness the electroencephalogram (EEG) shows relatively low-voltage, high-frequency, fast activity, reflecting an active cerebral cortex busy with perception and cognition. Slow synchronized oscillatory activity is either at a minimum or occurs only transiently in small groups of neurons (Figure 51–1). Relaxing or closing the eyes may produce alpha waves, especially over the visual cortex, indicating relatively synchronous rhythmic activity in the underlying cortical networks.

To describe sleep quantitatively and to distinguish its stages, sleep researchers routinely use three measures: brain activity measured by the EEG (see Chapter 50), eye movements recorded by the electro-oculogram (EOG), and muscle tone measured by the electromyogram (EMG). These three measures are used because of their reliability, ease of recording, and discriminatory power.

Non-REM Sleep Has Four Stages

Based on these measures, sleep is subdivided into five stages. Stages 1 to 4 comprise non-rapid eye movement (REM) sleep, while stage 5 is REM sleep. Stage 1 sleep is the transition between waking and sleep, the period in which sleep is thought to be imminent but not yet developed. During stage 1 the EEG exhibits a decrease in the high-frequency activity that characterizes the waking state. Stage 2, the first true stage of sleep, is marked in the EEG by the onset of spindle waves, 7-15 Hz oscillations over a period of 1-2 seconds that resemble a spindle of thread, and K-complexes (Figure 51–1). Spindle waves and K-complexes reflect slow, synchronized oscillations of neuronal and synaptic activity within the thalamus and cerebral cortex. This state is the result of the relaxation and general hyperpolarization of neurons and neuronal networks that follow gradual inactivation of the brain mechanisms of arousal. During stage 2 sleep muscle tone decreases, and the eyes slowly roll back and forth. Respiration becomes more regular and slows (Figure 51–2), and body temperature begins to fall.

Stage 3 sleep is heralded in the EEG by the appearance of a significant fraction of delta wave oscillations (0.5–4 Hz). These signal a further reduction in arousal

processes in the brain and increased synchronization of cortical and thalamic activity. A predominance of delta waves (> 50% of the time in the EEG) indicates that the person is in *stage 4 sleep*, the deepest stage. During stages 3 and 4 respiration continues to be slow and regular, heart rate slows, muscles relax, and temperature slowly drifts downward (Figure 51–2).

The progression from waking to stage 4 sleep at the beginning of the night typically occurs relatively quickly—over the first 30 minutes (Figure 51–1). After approximately 30 minutes in stage 4 sleep the sleeper ascends quickly through all four stages of sleep. Instead of waking, however, the sleeper now enters a unique stage known as rapid eye movement or REM sleep, a period in which dreams can become vivid, even bizarre.

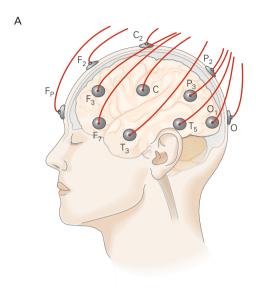

Rapid eye movement (REM) sleep was discovered in 1953 when Eugene Aserinsky and Nathaniel Kleitman first recorded the EEG and EOG of sleeping adults and observed that during sleep these tests showed changes in activity approximately four to five times per night (changing to a state of higher frequency and lower amplitude similar to that of the waking state). During this "activated" period the eyes dart back and forth, thus giving this stage its name. Sleepers roused from REM sleep report experiencing vivid dreams approximately 80% to 95% of the time.

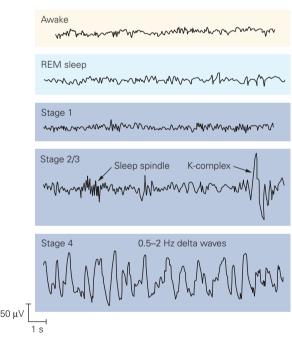

Interestingly, REM sleep is associated with an almost complete loss of muscle tone, owing to inhibition of the spinal motor neurons by descending pathways. Apparently the motor neurons in the brain stem that control eye movements are not inhibited, because the eyes move during REM sleep. During REM sleep temperature regulation is at a low point, and body temperature begins to fall further still.

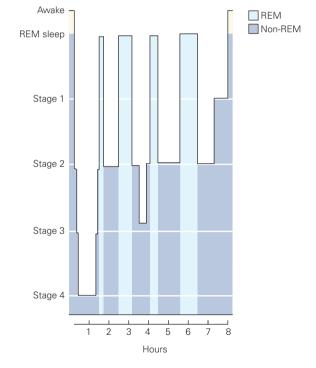

Although sleep can be segregated into five stages, the REM stage is so distinctive that sleep is often separated into two phases, referred to simply as REM and non-REM (or NREM) sleep. The cycle of sleep—the non-REM sequence from stage 1 to stage 4 and the reverse sequence followed by a brief period of REM sleep—occurs repeatedly during the night, in a pattern that is best described as a damped oscillation. As the night progresses, the depth of non-REM sleep decreases and the duration spent in REM sleep increases (Figure 51–1). As a result of this pattern, and the fact that it is necessary to wake up to remember your dreams, the dreams that take place in the morning are the ones most often remembered.

REM and Non-REM Dreams Are Different

In adults REM sleep occupies approximately 25% of the total sleep time. Most people would be surprised

В

Figure 51–1 The electrical activity of the brain is distinctive during wakefulness and each of the five stages of sleep.

A. Electrodes are placed systematically on the scalp for recording the electroencephalogram (see Figure 50–1). Each trace of the electroencephalogram (EEG) is actually the difference between neighboring electrodes, a technique that removes noise. When the subject is awake with eyes open, the EEG exhibits low-voltage, higher-frequency activities. Stage 1 sleep is characterized by a slight slowing of frequencies, whereas stages 2 and 3 sleep are characterized by spindle waves and

K-complexes as well as increases in other slow rhythms. During stage 4 sleep slow rhythms become very prominent. During rapid eye movement (**REM**) sleep is similar to that during waking.

B. Over the course of the night several cycles of deepening and lightening of sleep occur as a damped oscillation, known as the *ultradian rhythm*. Upon falling asleep, non-REM sleep deepens, followed by REM sleep, and then a period of lightened non-REM sleep. Each cycle is approximately 90 minutes. (Adapted, with permission, from Purves et al. 1997 and 2004.)

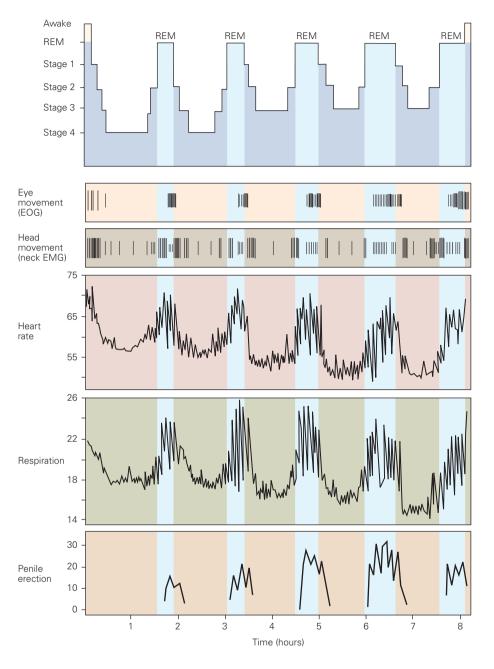

Figure 51-2 Physiological changes during sleep. Sleep consists of several cycles between stages 1 and 4 and rapid eye movement (REM) sleep. As sleep deepens, eye movements become less prominent; movements of the head, heart rate, and respiration all decrease. As the level of sleep lightens, these trends reverse. During REM sleep heart rate and respiration increase, as does penile erection. Neck movements can occur just before and after an episode of REM sleep, whereas during REM sleep muscle tone is very low. (EOG, electrooculogram; EMG, electromyogram.) (Adapted, with permission, from Purves et al. 2004.)

to find that they had vivid dreams for approximately 2 hours every night. Indeed, the inability to remember dreams (unless awakened) is one of the great mysteries of sleep.

Analysis of dreams and their content have revealed some surprising results. Most people believe that dreams are only occasional and fleeting occurrences of highly bizarre or emotional content, in which the entire scenario is dreamt in an instant. In reality, specific dreams recur with a regular and predictable periodicity, and mostly reflect everyday events. Even the fleeting nature of dreams is a misperception. Events in dreams occur over a period of time that is about as long as they would in real time. Only a small percentage of dreams contain bizarre and fantastic elements.

Dreams occur in both REM and non-REM sleep but the characteristics of REM and non-REM dreams differ. REM dreams are relatively long, primarily visual, somewhat emotional, and usually not connected to the immediate events of the everyday life of the dreamer. These resemble what Freud referred to as the latent content of the dream. Non-REM dreams are shorter, less visual, less emotional, more conceptual, and usually related to the current life of the dreamer. They resemble what Freud referred to as the day's residues, or the manifest content of the dream. This conceptual, "thought-like" mentation can occupy up to 50% of non-REM sleep.

What sensory modalities are experienced during dreams in REM sleep? Vision is preeminent, occurring in all dreams (except, of course, in the congenitally blind), whereas auditory events occur in approximately 65%, vestibular 8%, and temperature 4%; tactile, olfactory, and gustatory experiences are rare (only 1% each). The emotional content of dreams varies from anxiety (14%), to surprise (9%), joy (7%), sadness (5%), and shame (2%). Men experience penile erections, and women experience the physiological counterparts of sexual arousal during REM sleep. The regularity of penile erection during REM sleep (Figure 51-2) can help determine if impotence in a patient has a psychological or physiological origin. The emotional content is organized at several levels of the central nervous system but is, for the most part, unrelated to the specific content of the dream.

Sleep Obeys Circadian and Ultradian Rhythms

Sleep is a circadian behavior that is composed of cyclical or ultradian stages. In all species the period of sleep is dictated by the rotation of the earth and time clues (German, zeitgebers) that indicate the day-night cycle. The principal zeitgeber is the daily rising of the sun. It was once thought that the circadian rhythms of plants and animals are strongly or completely driven by the rising and setting of the sun. However, in 1729 the Swiss astronomer Jean-Jacques d'Ortous de Mairan observed that even in the dark the leaves of plants move according to a diurnal cycle. Since then endogenous rhythms of about 24 hours (ie, circadian rhythms) have been found to be prevalent throughout the plant and animal kingdoms. Circadian rhythms seem to have evolved so as to maximize the use of the day-night cycle by anticipating the rising and setting of the sun, even without clear signals from sunlight or other zeitgebers.

The features of the circadian rhythm of sleep in human beings, in the absence of zeitgebers, has been documented by a few brave individuals willing to live in isolation in specially constructed rooms in labs or caves. These rooms contain no clues as to the time of day in the outside world—no clocks, windows, radios, televisions, e-mail, Internet, or sounds that would tell

subjects the time in the outside world. Under these conditions subjects were allowed to sleep and be active whenever their body dictated. Interestingly, the circadian rhythm persists, but its duration varies among subjects and is typically slightly longer (eg, 25 hours) than that of the normal day-night cycle, causing each person in isolation to slowly drift out of phase with the outside environment. Reexposure to the external day-night cycle rapidly resets the sleep-wake cycles (Figure 51–3A).

The sleep-wake cycle is not the only circadian rhythm in the body. Many other physiological processes also exhibit daily maximums and minimums. The level of arousal, the ability to do cognitive tasks such as math problems, body temperature, hormone release, and kidney function all follow endogenous 24-hour rhythms that normally are synchronized to the day-night cycle.

How do sleep and other circadian rhythms become synchronized to the day-night cycle? A small number of retinal ganglion cells (see Chapter 26) respond directly to light and project to the suprachiasmatic nucleus in the hypothalamus (Figure 51-3B). It is this pathway, described in detail later, that synchronizes the circadian rhythmicity with the day-night cycle. Although rare, some people with tumors or lesions of the hypothalamus lose the circadian rhythmicity of their sleep-wake cycle and therefore sleep for short periods throughout the day. Other people, equally rare, have a normal circadian rhythm in their sleep-wake cycle but are unable to synchronize it with the day-night cycle of their environment. The phase relationship between their own endogenous need to sleep, and the time of day, changes continually. Perhaps in these people the neural path conveying light information to the suprachiasmatic nucleus is defective.

Jet lag demonstrates other properties of our circadian rhythm. Travel to a distant time zone disrupts the synchrony of one's circadian rhythm with the day-night cycle. One may temporarily experience excessive sleepiness during the day, hunger at the wrong times, cold despite being in a warm environment, and awakenings in the middle of the night despite sleep deprivation. This feeling of being "out of phase" is common and has a physiological basis. Flying west is generally easier than flying east, presumably because our endogenous rhythm is approximately 25 hours. When flying west we take advantage of this long rhythm by staying up late and sleeping in. Indeed, many individuals practice this on a weekly basis—staying up late and sleeping in on the weekend. The jarring experience of the "Monday morning blues" results from a rapid shift in the

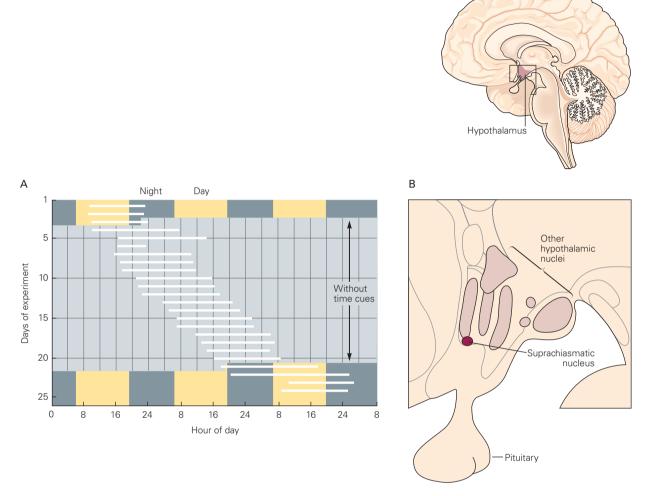

Figure 51–3 The endogenous circadian rhythm of sleep in humans.

A. A human volunteer isolated in an underground bunker is initially exposed to a normal day-night cycle and exhibits a circadian period of wakefulness (white bar) that is synchronized with the day-night cycle. However, following removal of external cues (after day 3) the volunteer's circadian cycle lengthens from 24 hours to approximately 26 hours (days 4–21). Because the endogenous cycle of the volunteer is longer than that of the

normal day-night cycle, the period of wakefulness slowly drifts out of phase. Following reintroduction of environmental cues to the normal day-night cycle, the subject's periods of wakefulness once again become synchronized to the day-night cycle. (Adapted, with permission, from Aschoff 1965.)

B. The suprachiasmatic nucleus in the hypothalamus is the master circadian clock of the nervous system. (Adapted, with permission, from Purves et al. 1997.)

circadian cycle and perhaps a bit of sleep deprivation thrown in as well.

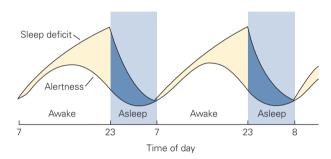

Sleepiness—the drive to sleep—depends on several factors. Two of the strongest are the time since the last full period of sleep and the circadian rhythm. We therefore can think of the drive to sleep as two separate processes: a "sleep deficit" that slowly builds up without sleep and dissipates with sleep, and a circadian rhythmicity in arousal. The difference between

these processes reflects the sleep drive. After a full night of sleep the sleep deficit should be very low. In the morning our level of arousal slowly increases as does our sleep deficit. Because sleep deficit and alertness increase together, the difference between these two processes—the drive to sleep—is small and therefore weak. Toward evening, however, our sleep deficit continues to increase, and the circadian rhythm of arousal begins to wane, resulting in a larger and

larger sleep drive (Figure 51–4A). Sleeping a full night once again removes the sleep debt, and the process starts over.

If a night of sleep is missed, one is likely to find that at approximately 3–4 a.m. it is nearly impossible to stay awake. This is because the sleep deficit is high and continues to increase, while the circadian rhythm in arousal (and other body functions such as temperature) is at a low point. Thus the sleep drive is high (Figure 51–4B). Sleep once again restores the balance, relieving this built-up sleep pressure.

A Sleep/wake cycle

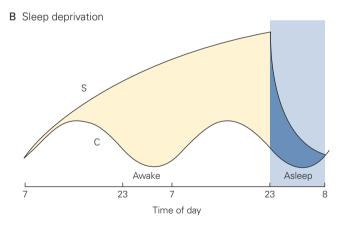

Figure 51–4 Hypothetical model of the circadian rhythmicity of the sleep drive. The difference between two interacting circadian processes—alertness and sleep deficit—determines sleep drive. (Adapted, with permission, from Daan et al. 1984.)

A. During a normal sleep-wake cycle the drive to sleep (yellow) accumulates during the day and declines during sleep (blue) such that the desire to sleep is greatest at bedtime and least on wakening.

B. Missing a night of sleep results in a continual build up of the sleep deficit (curve S) while the endogenous circadian rhythm of arousal (curve C) persists. As a result, over the period of wakefulness the sleep drive (the difference between S and C curves) varies. It is greatest in the middle of the night of missed sleep as well as at normal bedtime on the second evening.

The Circadian Rhythm Clock Is Based on a Cyclic Production of Nuclear Transcription Factors

The search for the neural basis of circadian rhythmicity of sleep has led to one site, the suprachiasmatic nucleus (Figure 51–3B), so named because of its location just above the optic chiasm, the place where the optic nerves cross underneath the hypothalamus.

The firing frequency of neurons in the suprachiasmatic nucleus follows an endogenous circadian rhythm (see Figure 51-6C). Thus the 20,000 neurons in the suprachiasmatic nucleus make up the master clock for circadian rhythms. They are the critical pacemaker for organizing sleep into a circadian pattern. The circadian activity of these neurons is entrained by environmental stimuli such as light, as measured by release of the transmitter vasopressin (see Figure 51-6C). Lesioning this nucleus in animals causes complete loss of the circadian rhythmicity of sleep-wake cycles. Animals with these lesions continue to have a normal daily amount of sleep, but sleep occurs randomly throughout the day and night. Transplantation of the suprachiasmatic nucleus from another animal can restore a circadian sleep rhythm, with the host animal adopting the sleep-wake cycle of the donor.

The suprachiasmatic nucleus is organized into distinct functional groups and acts as the controller for the rhythmic oscillations of clocks located in other organs in the body. These "peripheral" clocks are capable of maintaining their own circadian rhythms for only a few days without input from the suprachiasmatic nucleus.

Like a grandfather clock, the biological clocks that control circadian rhythms have many parts: A complex set of transcription factors, proteins, kinases, phosphatases, and regulatory molecules that have been remarkably conserved throughout the evolution of species. A number of molecules that play key roles in the clock mechanism have been identified over the last 20 years, largely from experiments in the fruit fly *Drosophila* and the mouse. The essence of the clock mechanism in the suprachiasmatic nucleus, as well as in other organs, is a pair of transcriptional feedback loops; one forms the core circadian mechanism whereas a second forms a modulatory loop that stabilizes the circadian rhythm. Such interlocking feedback loops are quite similar in flies and mammals (see Chapter 3).

At the center of the two loops are two transcriptional activators, CLOCK and BMAL1. These transcription factors bind to each other and form a heterodimer that enhances transcription of the mouse gene *per* (*mPer1*–3) and cryptochrome genes (*mCry1*–2), thereby increasing the cytoplasmic concentrations of the PER

and CRY proteins. PER and CRY form heterodimers, reenter the nucleus, and inhibit CLOCK and BMAL1, thus repressing PER and CRY transcription. This sequence creates the core circadian mechanism in which *Bmal1* RNA reaches a peak 12 hours out of phase with *mPer* and *mCry* RNA. CLOCK and BMAL1 are also at the center of the modulatory loop that modifies the levels of CLOCK/BMAL1 heterodimers. Mutations in genes in the stabilizing loop do not disrupt circadian rhythms to the same degree as those in the core loop.

Once the central clock in the suprachiasmatic nucleus generates the rhythm and the environmental light-dark cycle synchronizes it, this information must be communicated to various systems through humoral or electrical signals. To achieve this, the rhythmic molecular signal is transduced into electrical activity in suprachiasmatic nucleus neurons and then transmitted to other brain regions through action potentials.

A number of areas in the hypothalamus receive input from the suprachiasmatic nucleus and play a role in integrating the output of the suprachiasmatic nucleus. For example, a large number of axons from the suprachiasmatic nucleus terminate in the dorsal and ventral subparaventricular zones of the hypothalamus. The dorsal subparaventricular zone appears to project to areas that are important for circadian rhythms of body temperature, whereas the ventral subparaventricular zone and the downstream dorsomedial nucleus of the hypothalamus are important in the sleep-wake cycle. The dorsomedial nucleus may serve as a common final pathway for a number of circadian rhythms as lesions of this nucleus interrupt circadian rhythms for feeding, locomotion, and corticosteroid secretion as well as the sleep-wake cycle.

The Ultradian Rhythm of Sleep Is Controlled by the Brain Stem

Our level of arousal can best be described by a circadian cycle of sleep and wakefulness, and an ultradian rhythm in the sleep period consisting of a damped oscillation between non-REM and REM periods (Figure 51–1B). Although the suprachiasmatic nucleus is critical to the generation and synchronization of circadian rhythms, it is not the generator of sleep and arousal, for animals without a functional suprachiasmatic nucleus continue to exhibit these states.

The search for brain structures essential for arousal and for the ultradian rhythm of sleep focused on the brain stem and hypothalamus. In 1949 Horace Magoun and Giuseppe Moruzzi demonstrated that electrical stimulation of anterior portions of the brain stem results in arousal of the forebrain (see Chapter 46).

They dubbed this afferent pathway the "ascending activating system." This pathway in concert with portions of the hypothalamus appears to be responsible for maintaining the waking state. By cutting the brain at different levels, Michel Jouvet in France and others localized the neuronal groups needed to generate the brain activation, muscle atonia, and rapid eye movements of REM sleep to a restricted region of the pons and medulla.

Putting the two findings together it became clear that the brain stem is a central organizer for the control of arousal as well as the other components of REM sleep. For example, chemical stimulation of particular portions of the brain stem can cause a state similar to REM sleep, complete with activation of the EEG and muscle atonia (because of descending inhibition of spinal motor neurons). Lesions of the same region can result in an animal that lacks the muscle atonia of naturally occurring REM sleep, resulting in an animal that acts out its dreams. Similarly, persons with REM behavior disorder, an unusual sleep disorder in humans, become physically active during REM sleep.

Although the precise neuronal circuits generating the circadian and ultradian rhythms of sleep and arousal are not known, we do know some of the major cellular components. Many cholinergic neurons within the brain stem and basal forebrain fire in anticipation of either waking or REM sleep. These cholinergic neurons in turn project throughout the forebrain, including the thalamus, cerebral cortex, and hippocampus. The release of acetylcholine (ACh) depolarizes, and therefore activates, many of these target cells.

Noradrenergic and serotonergic neurons of the brain stem and histaminergic neurons of the hypothalamus also project widely throughout the nervous system and modulate neuronal excitability during different phases of the sleep-wake cycle. These cells fire in anticipation of the waking state and maintain a regular, almost pacemaker-like, discharge rate throughout waking. The discharge rate of the noradrenergic cells increases in response to novel stimuli, while that of the serotonergic cells increases in response to changes in blood pH. Finally, the ventral lateral preoptic nucleus of the anterior hypothalamus includes cells that inhibit ascending activating networks, thus promoting sleep.

Although the rate of firing of noradrenergic, serotonergic, and histaminergic neurons increases in anticipation of and during the waking state, it decreases ahead of REM sleep and may even become completely silent. These cells are therefore known as REM-OFF cells. Other neurons, some of which are cholinergic, discharge in anticipation of and during the period of REM sleep and are known as REM-ON cells (Figure 51–5).

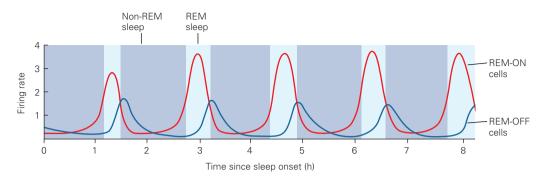

Figure 51–5 Firing rate of brain stem neurons involved in the onset and offset of REM sleep. Certain cholinergic neurons (red line) in the brain stem discharge strongly during periods of REM sleep but less so during non-REM sleep and thus are known as REM-ON cells. In contrast, certain noradrenergic

and serotonergic cells (**blue line**) become almost completely silent near the onset of REM sleep and then reach their maximum activity at the offset of each REM period and therefore are known as REM-OFF cells. (Adapted, with permission, from McCarley and Massaguoi 1986.)

Presumably, the discharge of these REM-ON cells is responsible for the activation of the forebrain during REM sleep. Interestingly, the final step of Otto Loewi's experiment demonstrating that ACh is a chemical transmitter came to him in a dream. Thus ACh participated in its own discovery.

The cyclicity of REM and non-REM sleep can be modeled as an antagonistic interaction between REM-OFF (histaminergic, noradrenergic, and serotonergic) cells and REM-ON (cholinergic) cells.

During REM sleep phasic bursts of action potentials occur throughout the forebrain in association with rapid eye movements. These bursts of activity are strongest within the pontine and geniculate nuclei and the occipital (visual) cortex and therefore are known as ponto-geniculate-occipital (PGO) waves. These waves appear to be initiated by the phasic discharge of brain stem cholinergic neurons; the activation of nicotinic ACh receptors on cells in the forebrain results in a rapid depolarization of the postsynaptic cells. During waking PGO waves may result from activation of brain stem mechanisms mediating shifts in attention associated with eye movements.

Sleep-Related Activity in the EEG Is Generated Through Local and Long-Range Circuits

Sleep is associated with characteristic patterns of activity in the EEG. Non-REM sleep is dominated by sleep spindles, appearing as 1–2 second periods of 7–14 Hz waxing and waning oscillations, and delta (0.5–4 Hz) or slower (< 1 Hz) oscillations. How and where are these EEG rhythms generated?

Slices of forebrain isolated from the rest of the brain can generate activity similar to that which occurs during sleep. For example, thin slices of either the thalamus or the cerebral cortex generate spontaneous activity that resembles the EEG rhythms of non-REM sleep (Figure 51–6). Thus at least some of the spontaneous firing patterns of the forebrain during non-REM sleep result from local neuronal networks alone, without requiring external modulatory input. These firing patterns reflect the basal, or resting, state of the forebrain when it is relieved of the barrage of neurotransmitters from other structures in the waking state and REM sleep.

In fact the progression from waking to stage 1 to stage 4 sleep is the consequence of a gradual withdrawal of modulatory neurotransmitters, allowing forebrain neurons to gradually hyperpolarize and shift into the basal state and the generation of the slow EEGrhythms of non-REM sleep. Once the activity of these neurons becomes slow and synchronized, cognitive function is reduced or abolished. The observation that waking and REM sleep are active states that must be maintained by ongoing activity in modulatory pathways fits well with our intuitive notion of sleep. We isolate ourselves from stimuli and relax into a hopefully blissful repose.

The purpose, if any, of rhythmic brain activity during sleep is not yet known. It may merely be the expression of the system properties of neural circuits that are idle during sleep. Or rhythmic activity may serve to keep cells active without the brain being sensitive to external stimuli. This activity could tune or recalibrate the brain during sleep—allowing useless information to be forgotten and important facts to be retained.

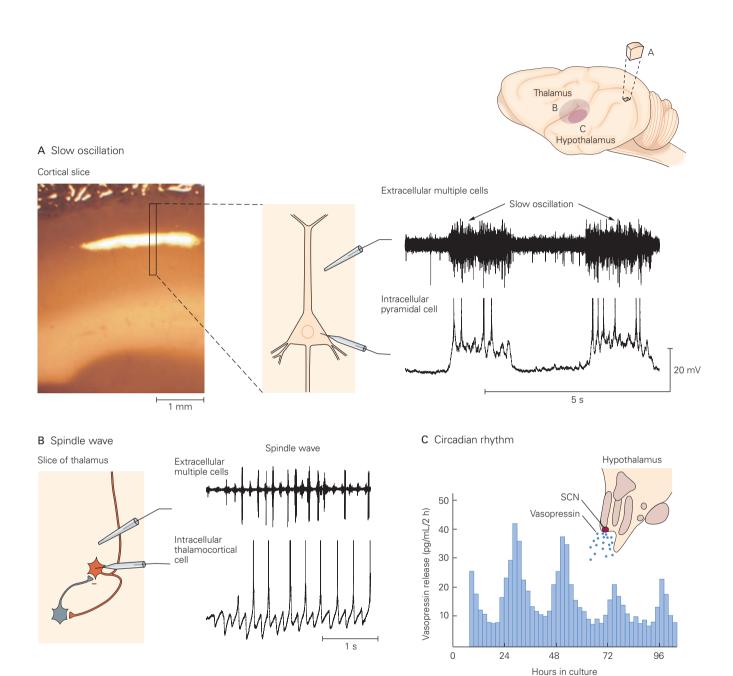

Figure 51–6 Cellular mechanisms of electroencephalogram rhythm generation during sleep.

A. The slow oscillation that underlies the slow waves of the EEG in vivo typically occurs during slow-wave sleep and is generated by the massively recurrent excitatory and inhibitory networks of the cerebral cortex. The slow oscillation is evident in vitro in extracellular recordings from a number of cortical cells made simultaneously with an intracellular recording of a single pyramidal cell. The picture of a cortical slice shows the sites of cell recordings. (Reproduced, with permission, from Sanchez-Vives and McCormick 2000.)

B. A spindle wave is evident in vitro in extracellular recordings from a number of cells made simultaneously with the

intracellular recording of a single thalamocortical cell in a slice of the thalamus. This pattern of activity typically originates in the thalamus during slow-wave sleep and is transmitted to the cerebral cortex, where it appears in the EEG (see Figure 51–1A). Spindle waves are generated exclusively by the interaction of thalamic excitatory and inhibitory circuits. (Reproduced, with permission, from von Krosigk et al. 1993.)

C. A circadian rhythm is maintained in vitro as evidenced by rhythmic release of vasopressin from neurons in the isolated suprachiasmatic nucleus (SCN), demonstrating that these neurons have endogenous mechanisms for timing the 24-hour cycle. (Reproduced, with permission, from Earnest and Sladek 1987.)

Sleep Changes with Age

Sleep shows striking and characteristic changes with age. As every new parent quickly learns, the sleep of a newborn, although plentiful (16–18 hours a day), is distributed almost randomly throughout the day. What the parent may not realize, however, is that more than 50% (8–9 hours) of that sleep is spent in a REM-like state (Figure 51–7).

Sleep recordings from a premature infant exhibit an even higher percentage of REM sleep, indicating that in utero the fetus spends a large fraction of the day in a brain-activated but movement-inhibited state. As neuronal activity influences the development of functional circuits in the brain, it is reasonable to think that the spontaneous activity of the immature brain during sleep facilitates the development of circuits.

By approximately 4 months of age the average baby begins to show diurnal rhythms that are synchronized with day and night, much to the relief of weary parents. The total duration of sleep gradually declines, however, so that by 3 to 5 years of age the child may sleep 10 to 12 hours a day. At these early ages sleep is deep; stages 3 and 4 are prominent, with an abundance of delta waves in the EEG. As a result, children are not easily wakened by environmental stimuli.

Even though children ages 3 to 5 years may spend a large percent of their sleep in REM sleep, only approximately 33% of awakenings result in recall of dreams. These dream reports are brief, and contain virtually no story, self-representation, or interaction between the characters in the dream. However, by the age of 7 to 9 years the dream reports take on more of the qualities of those of adults, including the ability to analyze, abstract, manipulate, and construct visuospatial

images or ideas. The content of dreams parallels the development of cognitive skills in the dreamer.

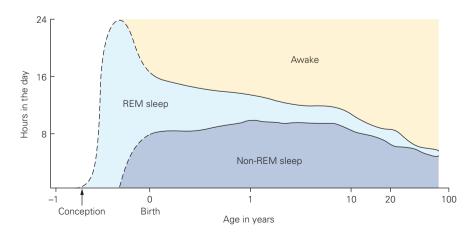

With age, sleep becomes less deep and more fragmented. The percent of time spent in stages 3 and 4 of non-REM sleep may drop dramatically, especially in old age. This results in a significant decrease in the perceived quality of sleep and an increase in daytime sleepiness. Disorders of sleep, such as insomnia and sleep apnea, also become more prevalent with age.

The Characteristics of Sleep Vary Greatly Between Species

Although all animals have circadian rest periods, the similarity between these and human sleep decreases with evolutionary distance. Nevertheless, some scientists contend that all animals, from fruit flies to man, do in fact sleep. The duration of sleep and the behaviors associated with it vary widely between species. Sleep seems essential to life, but its precise features have been modified to fit the requirements of each species.

The sleep habits of more than 90 mammals have been studied. Some sleep in well-protected burrows (eg, moles and rabbits), whereas others sleep in the open in herds. Giraffes sleep only approximately two hours a day, cats sleep approximately 13 hours, and the brown bat sleeps almost 20 hours. Some mammals (eg, cattle) sleep with their eyes open. Some, such as dolphins and porpoises, sleep with only half of their brain at a time. Presumably this adaptation allows these sea mammals to continually swim to the surface for air. All mammals have clearly recognizable non-REM sleep and nearly all have REM sleep. One notable exception is the spiny anteater, which has only non-REM sleep.

Figure 51–7 The amount of time spent each day in waking, REM sleep, and non-REM sleep changes over life. The proportion of the day spent in sleep decreases with age, with a particularly dramatic decrease in REM sleep during the first few years of life. The time spent in different sleep periods before birth is not well known, although data from premature infants suggest that babies in utero spend a large percentage of their time in a REM-like state. (Adapted, with permission, from Hobson 1989.)

Birds also have REM and non-REM sleep, although during REM sleep they do not lose muscle tone completely, allowing them to remain perched. A state resembling non-REM sleep is recognizable in reptiles, amphibians, and fish, although REM sleep is not evident.

Nocturnal animals are active at night, exploiting an ecological niche, and sleep during the daylight. Other species, such as humans, make use of the abundant sunlight during the day and are diurnal.

Sleep Disorders Have Behavioral, Psychological, and Neurological Causes

More than half of the population experiences significant difficulties with sleep at least on occasion, and as many as one in five persons suffers from chronic sleep problems. Disruption of sleep and waking is the most prevalent health disorder in the United States. Falling asleep while driving, for example, is thought to be responsible for at least 100,000 traffic accidents every year. Lack of sleep was a contributing factor in the disasters at the Three Mile Island and Chernobyl nuclear power plants.

Millions of people struggle through daily life sleepy, and many are irritable or unmotivated owing to disruptions in sleep. As a result, sleep disorders are common in general medical practice. Most sleep problems have mundane causes and may simply require a change in habit. Others involve complicating factors such as shift work, depression, or substance abuse. Some sleep disorders now provide new insights into brain function.

As sleep is organized into several cyclical, roughly 90-minute periods of REM and non-REM sleep, each component can be disrupted. The most common disorders are related to a breakdown in the transition between sleep and waking, such as difficulty falling asleep or early morning wakening. More than half of adults experience insomnia at some point each year. Their sleep is either too short, difficult to obtain, or not refreshing. The lack of adequate or fulfilling sleep often leads to another common complaint: daytime sleepiness.

Other sleep disorders may represent a breakdown in specific neural circuits. For example, sudden activation of the inhibitory descending motor pathways during the waking state can lead to bouts of cataplexy (loss of muscle tone), which is often associated with narcolepsy (described below). The opposite can also happen. In REM behavior disorder the descending inhibitory motor pathways do not function during REM sleep, such that the affected individual may jump up and move about during vivid dreams.

In other sleep disorders circadian rhythmicity may fail, resulting in a phase advance or phase delay in the sleep-wake cycle. Finally, sleep may be associated with inappropriate or unwanted behaviors such as night terrors, sleep walking, tooth grinding, bed wetting, and so on. These unusual behaviors disrupt sleep and are collectively known as *parasomnias*.

Insomnia Is the Most Common Form of Sleep Disruption

Insomnia, the most common form of sleep disruption, can be prolonged and severe or temporary and mild, as in response to short-term stress. The incidence of insomnia increases with age and is more common in women. Insomnia can manifest as difficulty falling asleep, difficulty staying asleep through the night, or early morning awakening before sufficient sleep is obtained. Insomnia may result from physical or emotional complications or simply from poor sleep habits (eg, consumption of excessive caffeine, alcohol, or food, or exercising vigorously before sleep). Insomnia is often associated with depression where early morning awakening is common.

Benzodiazepines, commonly used as anxiolytics (mild tranquilizers), are also commonly used for short-term treatment of insomnia. Benzodiazepines facilitate the opening of $GABA_A$ (γ -aminobutyric acid type A) receptor-channels through a binding site separate from that for GABA. Although these drugs facilitate sleep, they also suppress stage 4 sleep. Chronic use may be habit-forming and lead to a lightening and fragmentation of sleep. A related compound, zolpidem (sold under the trade name Ambien), binds selectively to a subset of benzodiazepine receptors, does not suppress deep sleep, and is considered relatively selective for facilitating sleep. It is therefore safer than general benzodiazepines for treatment of insomnia.

Over-the-counter sleep aids are often antihistamines (H₁ histamine receptor antagonists). Antihistamines are sedative in some individuals because they antagonize the activation of H₁ receptors, which normally excite thalamic and other central neurons. Muscarinic ACh receptor antagonists also have sedative effects, although these vary between individuals. Anticholinergic actions are common to many psychoactive drugs, such as tricyclic antidepressants, and therefore these drugs are used for insomnia. As discussed earlier, activation of muscarinic ACh receptors in the brain has a general arousal effect by exciting the principal neurons and, in some parts of the brain, by inhibiting GABAergic inhibitory interneurons.

Excessive Daytime Sleepiness Is Indicative of Disrupted Sleep

Sleepiness during the day is the primary complaint of individuals seeking help at hospital sleep centers. The invention of electric lights has allowed people to stay active well into the night. The increasing demands of work, family, and social life along with ever increasing opportunities for entertainment have led to a dramatic shortening in the time spent asleep, from an average of 10 to approximately 7 hours.

This trend has led to a chronic sleep deficit in the average adult that affects not only mood and general feelings of well being, but also work or school performance. Sleep deficit can be dangerous, as when driving or operating machinery. Telltale signs of insufficient sleep include unusually short sleep-onset latencies (less than 15 minutes), the need to sleep in on weekends, overuse of stimulants such as caffeine, and dependence on an alarm clock to wake up in the morning.

Excessive daytime sleepiness is a symptom of several underlying sleep disorders including sleep apnea, narcolepsy, and restless leg syndrome. Sleep apnea and restless leg syndrome are two of the most prevalent disorders that lead to daytime sleepiness, largely through a reduction in the quantity and quality of sleep. Narcolepsy is present in only a small fraction of the population but is devastating in its negative effects.

The Disruption of Breathing During Sleep Apnea Results in Fragmentation of Sleep

Reduction of muscle tone can result in either an annoying disturbance of sleep, as in snoring, or in greatly disturbed sleep, as in sleep apnea (cessation of breathing). Approximately 4% of middle-aged men (2% of middle-aged women) have sleep apnea. At older than age 65 years these percentages increase to more than 28% of men and 24% of women.

Sleep apnea is a serious condition, for it not only disrupts sleep but also can cause excessive sleepiness during the day, early morning headaches, depression, irritability, sexual dysfunction, and learning and memory difficulties. In severe cases sleep apnea can lead to cardiac dysfunction and be life-threatening.

The most common form of sleep apnea, *obstructive sleep apnea*, results from a physical obstruction of the pharynx. Breathing ceases for 10 or more seconds. A pathological condition involves at least 5 to 10 of these interruptions per hour. In *central sleep apnea* the disruption of breathing has a neurological origin. In either type of sleep apnea the decrease in blood oxygen

tension and increase in CO_2 leads to an arousal response (but not complete awakening). The period of apnea ends with a deep breath, and the sufferer then falls back into a deeper sleep, only to repeat the cycle once again (Figure 51–8).

These frequent disruptions cause fragmentation of sleep, a general decrease in quality of sleep, and therefore daytime sleepiness. Because the affected individual usually does not become fully awake with each apneic period, he may be completely unaware of the problem except for the resultant daytime sleepiness or the concern of a friend or spouse who observes an apneic spell. This pattern is usually easy to diagnose in a sleep laboratory.

REM sleep is especially conducive to sleep apnea owing to the characteristic reduction in muscle tone, which facilitates collapse of the airway. During REM sleep responses to hypoxia are reduced, and the response to increases in carbon dioxide levels (hypercapnia) is completely lost. In addition, the brain stem mechanisms responsible for regulation of blood O_2 and CO_2 levels are weakened, allowing these levels to drop well below those that would be tolerated in the waking state. Obesity can be a precipitating factor for obstructive sleep apnea because airflow through the pharynx is typically reduced.

Obstructive sleep apnea is treated by keeping the pharynx open with positive pressure through a face mask. This treatment can lead to an almost immediate reversal of the symptoms, a more restful sleep, and a reduction in daytime sleepiness. However, most patients eventually reject use of the mask because they find it too uncomfortable or claustrophobic to use consistently.

Narcolepsy Is Characterized by Abnormal Activation of Sleep Mechanisms

Narcolepsy occurs in approximately 0.04% of the population or approximately 120,000 people in the United States. It is characterized by a breakdown in the transition between waking and sleep. Sleep and sleep mechanisms invade daytime periods, often at inappropriate times, and sleep at night is fragmented and disrupted by multiple awakenings. Narcolepsy is characteristically manifested in five symptoms, some or all of which may be seen in any one individual.

The most prevalent symptom is excessive daytime sleepiness and irresistible "sleep attacks" during the waking hours. These sleep attacks (usually less than 20 minutes) can come at any moment and sometimes are a source of embarrassment. For example, falling asleep during conversation or at work may lead to

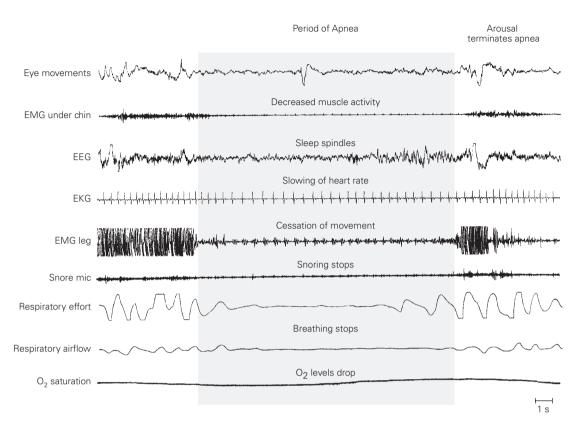

Figure 51–8 An episode of sleep apnea is captured in this polysomnogram, a simultaneous record of various bodily functions. Sleep apnea disrupts normal sleep patterns. The episode shown here includes cessation of breathing. Decreases in respiratory effort and airflow result in the cessation of snoring and a decrease in oxygen saturation. The slowing of the heart

rate and appearance of sleep spindles during the apnea episode indicate that the individual is asleep. The period of apnea is preceded and terminated by arousal and leg movements. (EEG, electroencephalogram; EKG, electrocardiogram; EMG, electromyogram.)

the incorrect assumption that the narcoleptic is uninterested in the conversation or in doing a full day's work. Sleep attacks are precipitated by any behavior that is relatively passive and boring such as watching television, driving a car, or studying for finals. Unfortunately, sleeping does not completely alleviate the tendency to have sleep attacks.

A second symptom, cataplexy, occurs in approximately 70% of narcoleptic patients. Cataplexy is a sudden bilateral loss of muscle tone, typically in the knees and face and neck, leading to a sagging of the jaw and falling to the floor. Consciousness is preserved, however, and the sufferer is typically awake but feels either unable or barely able to move. The onset of a cataplexic episode occurs over a couple of seconds; the episode itself lasts for seconds but in rare instances can last minutes. Emotion, most typically laughter, can provoke an attack, perhaps owing to the fact that during laughter there is a general decrease in muscle

tone. Cataplexy is thought to result from abnormal activation of the motor inhibition that normally occurs during periods of REM sleep.

Third, vivid dreamlike experiences may occur during the transition between sleep and waking. These events are known as either hypnagogic (sleep onset) or hypnopompic (sleep offset) hallucinations. What differentiates them from dreams is that the narcoleptic person is not fully asleep and is aware that he is not dreaming—the images seem real. The dreamlike experiences are typically bizarre, frightening, and unpleasant; they are predominantly visual, although auditory and tactile experiences are also frequent. As with dreams, sensations of smell or taste are rare. Hallucinations of this type may also occur in normal people at transitions between sleep and waking.

A fourth symptom, sleep paralysis, also typically occurs in the transition between sleep and waking (either going to sleep at night or waking in the morning). Unlike

cataplexy it is not triggered by emotion and episodes last longer, sometimes up to 10 minutes. As sufferers are unable to make even the smallest of movements, such as opening their eyelids or lifting a finger, the experience is frightening and unpleasant. As with cataplexy it is assumed that sleep paralysis results from inappropriate activation of the inhibitory descending motor pathways that are normally responsible for inhibiting movement during REM sleep. Sleep paralysis also occurs in non-narcoleptics (up to 30% of the general population).

The final symptom of narcolepsy is disturbed nocturnal sleep. Although narcoleptics may fall asleep quickly and often immediately fall into REM sleep (Figure 51–9), their sleep is interrupted by frequent arousals. For most narcoleptics these awakenings are brief, but some may stay awake for hours at night.

A diagnosis of narcolepsy requires a minimum of either (1) daytime lapses into sleep and cataplexy or (2) a pattern of excessive daytime sleepiness, sleep paralysis, or hypnagogic or hypnopompic hallucinations, and a polysomnogram demonstrating a short latency

to sleep and a period of REM sleep either at the beginning of sleep or shortly thereafter.

The different components of narcolepsy are treated with different pharmacological agents. The excessive sleepiness and sleep spells of narcolepsy are typically treated with central nervous stimulants such as amphetamines. These agents enhance the release of catecholamines and inhibit their reuptake. Cataplexy is treated with tricyclic antidepressants, which inhibit the reuptake of norepinephrine and serotonin and are potent inhibitors of REM sleep.

Both genetic and environmental factors contribute to narcolepsy. In only 1% of cases does narcolepsy run in a family and only approximately one-fourth of identical twins are concordant for narcolepsy. Thus narcolepsy genes appear to confer merely a susceptibility to narcolepsy, whereas environmental factors contribute strongly. By studying narcoleptic dogs, Emmanuel Mignot found that these animals have a defect in the gene coding for the hypocretin-2 receptor. Hypocretin-1 and -2 (also called orexin A and B) are neuropeptides produced in a small cluster of neurons

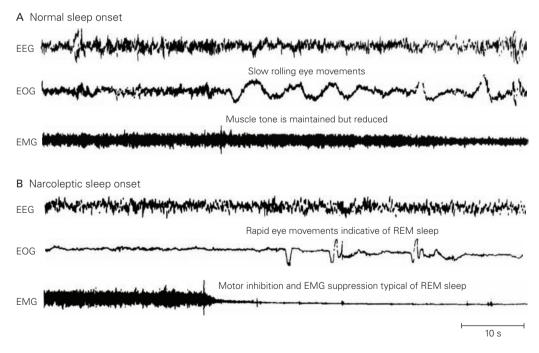

Figure 51–9 In narcoleptic patients sleep can initiate with REM sleep.

A. Sleep onset in a normal person is associated with slow rolling eye movements and a slow decrease in muscle tone.

B. Sleep onset in a narcoleptic is associated with a sudden decrease in muscle tone and the appearance of rapid eye

movements typical of REM sleep. The REM sleep that occurs at the beginning of sleep usually lasts 10 to 20 minutes, after which sleep progresses through stages 1 through 4 of non-REM sleep. (EEG, electroencephalogram; EMG, electromyogram; EOG, electro-oculogram.)

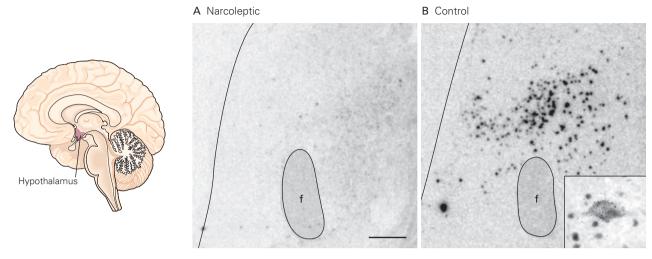

Figure 51–10 Narcolepsy is associated with a loss of hypothalamic neurons that produce the peptide hypocretin. A dramatic loss of neurons is evident in the brain of a narcoleptic compared to a normal brain. The inset illustrates the positive

identification of a hypocretinergic cell from a normal person. (f, fornix.) (Reproduced, with permission, from Peyron et al. 2000.)

within the hypothalamus that project widely throughout the brain, including the brain stem nuclei responsible for REM sleep (eg, locus ceruleus). Activation of hypocretin receptors in locus ceruleus and other neurons has a slow excitatory effect. Through an unknown mechanism, a loss of this or other modulatory actions of hypocretin results in the abnormal differentiation of sleep and waking typical of narcolepsy.

To study the role of the hypocretin system in feeding behavior, Masashi Yanagisawa and collaborators knocked out the genes for both hypocretin-1 and -2 in mice and found that these mice displayed symptoms typical of narcolepsy. In narcoleptic humans the cerebral spinal fluid levels of hypocretin are remarkably reduced even though the hypocretin genes are not mutated. Immunocytochemical examination of the brains of deceased narcoleptics has revealed a striking loss of hypocretinergic neurons (Figure 51–10).

Restless Leg Syndrome and Periodic Leg Movements Disrupt Sleep

Restless leg syndrome occurs in approximately 8% of the population and is characterized by an irresistible urge to move the legs. This symptom occurs during the day but is usually worse at night while resting in bed. The patient may feel relief only by moving the legs either in bed or by walking about. Approximately 80% of people suffering from restless leg syndrome also experience periodic leg movements in sleep, when the legs move for a few seconds every 10 to 20 seconds. These leg movements result in a lightening of sleep and therefore an increase in daytime sleepiness. The prevalence of restless leg syndrome and periodic leg movements increases greatly with age, becoming more common in the elderly.

Parasomnias Include Sleep Walking, Sleep Talking, and Night Terrors

Parasomnias are repeated disruptions of sleep that are relatively common and usually mild. They include sleep walking, sleep talking, confusional arousals, bed wetting, night terrors, and REM behavior disorder. Although not normally considered a sleep disorder, sudden infant death syndrome (SIDS) is an example of fatal respiratory failure that occurs during sleep (see Chapter 46).

Sleep walking, sleep talking, and confusional arousals are relatively common in children and typically occur during stages 3 and 4 sleep. These events may be precipitated by disturbing or arousing the child from deep sleep. For short events the EEG is a continued pattern of slow waves; for longer events the pattern changes to an "activated" pattern—low-voltage, desynchronized high-frequency activity—characteristic of waking. Usually sleepwalkers or talkers are unaware

of an event and have no memory of it. Speech is largely incoherent during an event; remarkably sleep walkers are often able to avoid colliding with objects.

Night terrors also occur in stages 3 and 4 sleep and are common in children (approximately 2–3%). The child cries as if in great fear, perhaps with eyes wide open and heart rate greatly elevated, for several minutes or longer. Even though they may appear awake, they are actually asleep. During the episode they are inconsolable, and attempts to calm or wake the child may only cause the screams and fearful behavior to worsen. The child usually does not remember the night terror, in contrast to remembering nightmares. Thus night terrors are typically much more difficult for the parent than for the child.

During REM sleep descending inhibition of motor neurons in the spinal cord normally prevents people from acting out their vivid dreams. This descending pathway may be damaged in people suffering from REM behavior disorder (usually men and elderly people). During REM sleep the body may become rigid or extremely tense and may exhibit prominent muscle twitching in association with the phasic eye movements of REM sleep. If the dream has intense physical activity, the patient may even get out of bed and injure himself or his bed partner with his vigorous activity. The mechanisms underlying REM behavior disorder are not yet known.

Circadian Rhythm Sleep Disorders Are Characterized by an Activity Cycle That Is Out of Phase with the World

The most frequent circadian rhythm disorder involves problems with entrainment to the day-night cycle. A patient may find it impossible to fall asleep until very late at night, for example 3 a.m. (delayed sleep phase disorder or DSPD) or impossible to stay awake past the early evening hours, for example 7 p.m. (advanced sleep phase disorder or ASPD).

The most prevalent disruption of normal circadian rhythms occurs in those who work either part-time or full-time during the night. In some individuals forcing a lifestyle that is out of phase with the natural day-night cycle can lead to several medical problems, including unstable mood, vigilance impairments, colds, high blood pressure, stomach problems, and weight gain. In general, shift workers also experience a higher incidence of workplace and automobile accidents because of increased sleepiness.

In rare cases patients may lack an endogenous circadian rhythm or may not be able to synchronize their rhythm with that of the environment. As one can imagine, these disorders cause great difficulties for those afflicted.

An Overall View

For a behavior that involves up to 25 years of our lifetime, it is surprising how much we do not yet fully understand about the functions of sleep. Sleep is essential for life, at least for rats. A rat deprived of all sleep dies after approximately 3 to 4 weeks owing to a breakdown in metabolic processes. In fact, sleep deprivation can cause death even more quickly than food deprivation.

In practice we sleep because we are sleepy, just as we eat or drink because we are hungry or thirsty. But the function of sleep is not to relieve sleepiness. Intuitively we think of sleep as restorative, but exactly what is restored is unknown. In addition to a restorative function, other functions have been proposed, including energy conservation, memory consolidation and sorting, recalibration of neuronal networks, and behavioral suppression during periods of the day for which the animal is not well adapted.

One explanation for this diversity of function is that bodily functions have, over evolution, become segregated into different portions of the day/night cycle so as to make efficient use of resources. Indeed, studies of gene expression reveal that a massive reorganization of the molecular and cellular biology of neurons occurs in the transition from alertness to sleep, suggesting that a similar marked reorganization occurs during sleep. Sleep is therefore likely to have many functions, just as waking does.

In fact, it may be useful to turn the question "Why do we sleep?" on its head and ask instead, "Why do we wake up?" In general, periods of waking are generated to accomplish a goal, for example, the procurement of food and housing, having a family, building a society; otherwise rest is warranted. By keeping the animal inactive during periods in which it is not well-suited for wandering about, sleep may ensure adequate rest and the reservation of energy stores. Waking up and becoming active can cost at least an additional 10% of energy. Given scarce food resources, ceasing activity for a significant fraction of each day can lead to a small but significant increase in survival. Thus sleep may be a light and short version of hibernation, an easily generated and reversible period of rest and energy conservation.

Another idea is called the protection hypothesis. Most animals are adapted for activity during the day or night. Being active at the wrong period brings with it considerable risks both from other animals (eg, predators) or environmental conditions (eg, cold during the night or heat during the day, or unseen objects because of low light levels).

Sleep involves the entire organism and in fact involves the family and society as a whole. Even so, many neuroscientists believe that sleep is of and for the brain. One neural function that is often proposed for sleep is memory consolidation. Disruption of sleep has detrimental effects on some types of learning, particularly procedural memory, although the stressful effects of lost sleep are always a confounding factor.

One idea holds that the spontaneous activity occurring in the sleeping brain is a type of neuronal exercise machine—keeping the brain "in tune" for the requirements of daily activities. By passing spontaneous patterned activity throughout neuronal circuits during the night, the brain can recalibrate the strength of synaptic connections as well as the electrophysiological properties of single neurons, resulting perhaps in the retaining of important information and the forgetting of irrelevant information. The presence of spontaneous patterns of neuronal activity in all animals during sleep, which is energetically more costly than neuronal silence, suggests that this activity plays an important functional role in sleep. Indeed, the spontaneous patterns of activity occurring in the brain during REM sleep are the neural basis of dreams.

The importance of REM sleep is a particularly thorny issue. Patients on some forms of antidepressant may go years with a near complete suppression of REM sleep without any marked deficits in the ability to form new memories or otherwise function normally. REM sleep may allow for a more immediate response to the environment during sleep (which has obvious survival value in the wild) because animals awakened from REM sleep are more responsive and show better sensory and motor function than those awakened from non-REM sleep. In a group of sleeping animals at least one or more of them may be in this state of readiness at any given moment and therefore able to alert the pack of an intruder.

Both REM and non-REM sleep are highly regulated processes that the brain and body appear to crave. Deprivation of REM sleep results in "REM rebound" in which the loss is made up by excessive REM sleep in the following night's sleep. This regulation suggests that REM sleep, and sleep in general, plays one or more critical functions. It remains for us, or rather our brains, to discover the nature of these functions so that we may more fully understand the more ethereal third of our lives.

VIII Development and the Emergence of Behavior

LL OF THE INNUMERABLE BEHAVIORS controlled by the mature nervous system—from the perception of sensory input and the control of motor output to cognitive functions such as learning and memory—depend on precise interconnections formed by many millions of neurons during embryonic and postnatal development.

More than a century ago, Santiago Ramón y Cajal undertook a comprehensive series of anatomical studies on the structure and organization of the nervous system, and then set out to probe its development. Modern developmental neuroscientists follow in Ramón y Cajal's footsteps, trying to uncover the processes underlying the formation of neural circuits. In the intervening years technical advances have made it possible to extend this inquiry to the molecular and genetic levels. During the past few decades there have been many striking advances in understanding the molecular basis of neural development. These advances include the identification of proteins that determine how nerve cells acquire their identities, how they extend axons to target cells, form synaptic connections, and have also provided insight into how synaptic connections are modified by experience.

Development of the nervous system depends on the expression of particular genes at particular times and places. This spatial and temporal pattern of gene expression is regulated by both hardwired molecular programs and epigenetic processes. The factors that control neuronal differentiation originate both from cellular sources within the embryo and from the external environment. Internal influences include cell surface and secreted molecules that control the fate of neighboring cells, as well as transcription factors that act at the level of DNA to control gene expression. External factors include nutrients, sensory stimuli, and social experience, the effects of which are mediated through patterned changes in the activity of nerve cells. The interaction of these intrinsic and environmental factors is critical for the proper differentiation of each nerve cell.

The recent progress in defining the mechanisms that control the development of the nervous system is due largely to molecular biological studies of neural function. To take but one example, the molecular cloning of genes encoding extrinsic factors (eg, secreted proteins) and intrinsic determinants (eg, transcription factors) has provided unanticipated insight into the differentiation of the nervous system. Moreover, the function of specific genes can now be tested directly in transgenic animals or in animals in which individual genes have been inactivated by mutation.

Other important advances have emerged from the analysis of simple and genetically accessible organisms such as the fruit fly *Drosophila* and the nematode worm *Caenorhabditis elegans*. Most of the key molecules that control the formation of the nervous system are found to be conserved in organisms separated by millions of years of evolution. Thus, despite the great diversity of animal forms, the developmental programs that govern body plan and neural connectivity are conserved throughout phylogeny. It is now clear that mutations in these genes are responsible for some degenerative and even behavioral disorders. Thus, studies of neural development are beginning to provide practical insight into neurological diseases and to suggest rational strategies for restoring neural connections and function after disease or traumatic injury.

There is, however, one major way in which humans—and to a lesser extent other mammals—differ from invertebrates and lower vertebrates. Although humans are quite helpless at birth, their capacities to learn, reason, decide and abstract are prodigious. A newly-hatched bird or fly is not remarkably different in its behavioral repertoire from its adult self, but no one could say that about a person. This is largely because the nervous system of a newborn human is something of a rough draft. The hard-wired circuits that lay out its basic plan are then modified over a prolonged postnatal period by experience, acting via neural activity. In this way, the experience of each individual can leave indelible imprints on his or her nervous system and the cognitive abilities of the brain can be enhanced by learning. These processes act in all mammals, and neuroscientists now use mice to probe the mechanisms that underlie them—but they are especially prominent and prolonged in humans. It may be that the prolonged period during which experience can sculpt the human nervous system is the most important single factor in making its capabilities unique among all species.

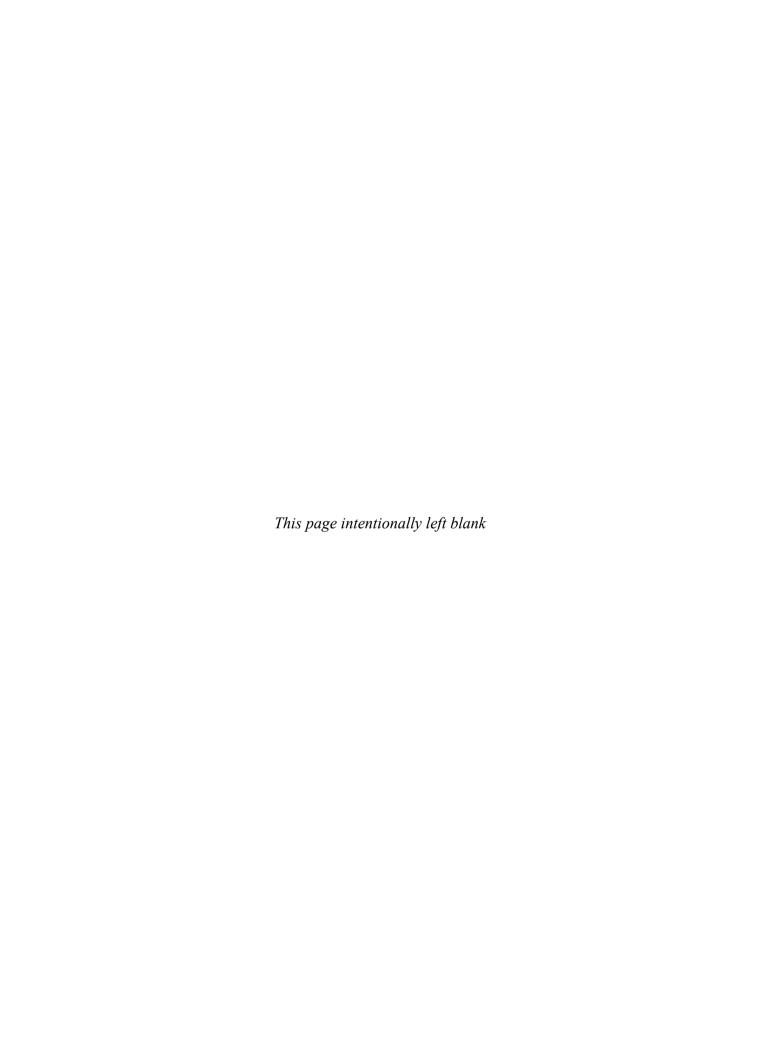

In human infants the experience-dependent acquisition of cognitive abilities is a social feature illustrated by the fact that infants learn better from other people than from television programs. The social interactions help language development, and as language development progresses, it helps social interactions. Until recently, analysis of this late, experience-dependent remodeling of the nervous system was primarily the province of psychology. Over the past several decades, however, neuroanatomists and neurophysiologists have made strides in understanding cellular changes that underlie it. Perhaps most exciting, continued progress in genetic and molecular technologies are now being applied to the topic. The issues have been more complex and harder to define than those encountered at the

early stages in neural development mentioned above, so the molecular revolution has been slower in coming to them—but the pace is now increasing rapidly. The implications of this new knowledge are great. For example, understanding how cognitive abilities are acquired during the preschool years helps us enhance the ability to educate all children. Moreover, there is increasing reason to believe that some behavioral disorders, such as autism or schizophrenia, may result in part from defects in the experience-dependent tuning of neural circuits during early postnatal life.

In Part VIII, we examine vertebrate neural development in a sequential manner. Beginning with the early stages of neural development, we concentrate on the factors that control the diversity and survival of nerve cells, guide axons, and regulate the formation of synapses. We then explain how interaction with the environment, both social and physical, modifies or consolidates the neural connections formed during early development. Depriving individuals of their normal environment during the early critical period of development can have profound consequences for the later maturation of the brain and thus for behavior. Finally, we examine factors, such as steroid hormones, that continue to influence the structure of the brain during early postnatal development and the biochemical changes that occur as the brain ages.

Patterning the Nervous System

The Neural Tube Becomes Regionalized Early in Embryogenesis

Secreted Signals Promote Neural Cell Fate

Development of the Neural Plate Is Induced by Signals from the Organizer Region

Neural Induction Is Mediated by Peptide Growth Factors and Their Inhibitors

Rostrocaudal Patterning of the Neural Tube Involves Signaling Gradients and Secondary Organizing Centers

Signals from the Mesoderm and Endoderm Define the Rostrocaudal Pattern of the Neural Plate

Signals from Organizing Centers within the Neural Tube Pattern the Forebrain, Midbrain, and Hindbrain

Dorsoventral Patterning of the Neural Tube Involves Similar Mechanisms at Different Rostrocaudal Levels

The Ventral Neural Tube Is Patterned by Sonic Hedgehog Protein Secreted from the Notochord and Floor Plate

The Dorsal Neural Tube Is Patterned by Bone Morphogenetic Proteins

Dorsoventral Patterning Mechanisms Are Conserved Along the Rostrocaudal Extent of the Neural Tube

Local Signals Determine Functional Subclasses of Neurons

Rostrocaudal Position Is a Major Determinant of Motor Neuron Subtype

Local Signals and Transcriptional Circuits Further Diversify Motor Neuron Subtypes

The Developing Forebrain Is Patterned by Intrinsic and Extrinsic Influences

Inductive Signals and Transcription Factor Gradients Establish Regional Differentiation

Afferent Inputs Also Contribute to Regionalization

An Overall View

VAST ARRAY OF NEURONS AND GLIAL CELLS is produced during development of the vertebrate nervous system. Different neurons develop in discrete anatomical positions, acquire varied morphological forms, and establish connections with specific populations of target cells. The diversity of neurons is far greater than that of cells in any other organ of the body. The retina, for example, has dozens of classes of amacrine interneurons, and the spinal cord more than a hundred motor neuron classes. Nevertheless, the true number of neuronal classes in the mammalian central nervous system remains unclear—perhaps more than a thousand.

The diversity of neuronal cell types underlies the impressive computational properties of the mammalian nervous system. Yet, as we describe in this chapter and those that follow, the developmental principles that drive the differentiation of the nervous system are begged and borrowed from those used to direct the development in other tissues. In one sense the development of the nervous system merely represents an elaborate example of the basic challenge that pervades all of developmental biology: How to convert a single cell, the fertilized egg, into the highly differentiated cell types that characterize the mature organism.

Indeed, the convergence of developmental biology and neural science has led us to appreciate that superficial differences in the structure of the nervous systems of diverse species belie the expression of commonly shared principles and mechanisms of neural development that have been conserved throughout evolution. Much of what we know about the cellular and molecular bases of neural development in vertebrates comes from genetic studies of so-called simple

organisms, most notably the fruit fly *Drosophila mela-nogaster* and the worm *Caenorhabditis elegans*.

Nevertheless, because the eventual goal of studies of neural development is surely to explain how the assembly of the nervous system directs and constrains human behavior, in this chapter and those that follow our description of the rules and principles of nervous system development focus primarily on vertebrate organisms.

The Neural Tube Becomes Regionalized Early in Embryogenesis

The nervous system begins to develop at a relatively late stage in the entire program of embryonic development.

Well before it forms, however, the primitive embryo has generated three main cell, or germ, layers—the endoderm, mesoderm, and ectoderm.

The *endoderm* is the innermost germ layer that later gives rise to the gut tube, as well as to the lungs, pancreas, and liver. The *mesoderm* is the middle germ layer that gives rise to muscle, connective tissues, and much of the vascular system. The *ectoderm* is the outermost layer that gives rise to the skin as well as to the columnar epithelium of the neural plate, the precursor of the central and peripheral nervous systems.

Soon after the neural plate forms it begins to fold into a tubular structure, the *neural tube*, through a process called neurulation (Figure 52–1). The caudal region of the neural tube gives rise to the spinal cord, whereas the rostral region becomes the brain.

Ectoderm
Mesoderm
Endoderm

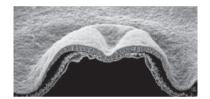

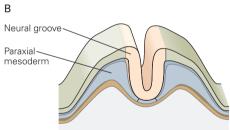

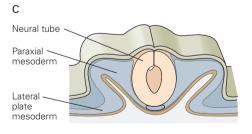

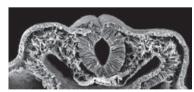

Figure 52–1 The neural plate folds to form the neural tube. (Electron micrographs of chick neural tube reproduced, with permission, from G. Schoenwolf.)

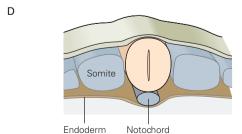

- A. Early in embryogenesis three germ cell layers—the ectoderm, mesoderm, and endoderm—lie close together. The ectoderm gives rise to the neural plate, the precursor of the central and peripheral nervous systems.
- **B.** The neural plate buckles at its midline to form the neural groove.
- **C.** Closure of the dorsal neural folds forms the neural tube.
- **D.** The neural tube lies over the notochord and is flanked by somites, an ovoid group of mesodermal cells that give rise to muscle and cartilage.

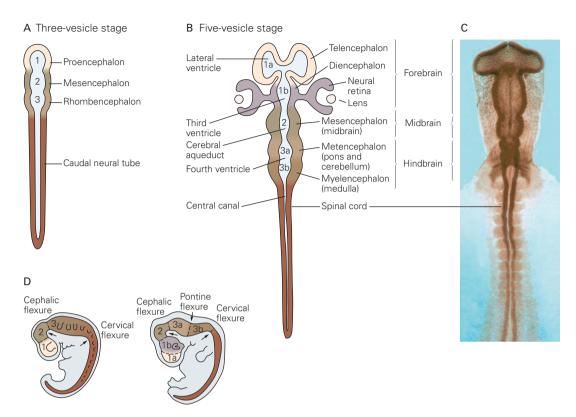

Figure 52-2 Sequential stages of neural tube development.

- A. At early stages of neural tube development there are three brain vesicles
- **B.** Shortly after, two additional vesicles form, one in the forebrain (giving rise to regions 1a and 1b) and the other in the hindbrain (giving rise to regions 3a and 3b).
- C. Top-down view of the neural tube of a chick embryo at the five-vesicle stage. (Reproduced, with permission, from G. Schoenwolf.)
- **D.** The neural tube bends at the cephalic, pontine, and cervical flexures.

During these early stages of neural development cells divide rapidly, although cell proliferation is not uniform. Individual regions of the neural epithelium expand at different rates and begin to form the various specialized regions of the mature central nervous system. Differences in the rate of proliferation of cells in rostral regions of the neural tube result in the formation of three brain vesicles: the forebrain (or prosencephalic) vesicle, the midbrain (or mesencephalic) vesicle, and the hindbrain (or rhombencephalic) vesicle (Figure 52–2A).

At this early three-vesicle stage the neural tube flexes twice: once at the *cervical flexure*, at the junction of the spinal cord and hindbrain, and once at the *cephalic flexure*, at the junction of the hindbrain and midbrain. A third flexure, the *pontine flexure*, forms later, and later still the cervical flexure straightens out and becomes indistinct (Figure 52D). The cephalic flexure remains prominent throughout development, and its persistence is the reason why the orientation of the

longitudinal axis of the forebrain deviates from that of the brain stem and spinal cord.

As the neural tube develops, two of the primary embryonic vesicles divide further, thus forming the five-vesicle stage (Figure 52–2B, C). The forebrain vesicle divides to form the telencephalon and diencephalon, and the hindbrain vesicle divides to form the metencephalon and myelencephalon. Together with the spinal cord these subdivisions make up the major functional regions of the mature central nervous system (see Chapter 15). These functional domains are the products of progressive patterning and subdivision of the neural tube, developmental events that are regulated by a variety of secreted signals.

Secreted Signals Promote Neural Cell Fate

As with other organs, the emergence of the neural plate is the culmination of a complex molecular program that

involves the tightly orchestrated expression of specific genes within ectodermal cells. The entire nervous system derives from a restricted region of the ectoderm.

Early in development ectodermal cells are faced with the choice of whether to become neural or epidermal cells. This decision is arguably the most fundamental step of neural development, and one that has been the subject of intense study for nearly 100 years. Much of this interest has focused on a search for signals that control the fate of ectodermal cells.

We now know that two major classes of proteins work together to promote the differentiation of an ectodermal cell into a neural cell. The first are *inductive factors*, signaling molecules that are secreted by nearby cells. Some of these factors are freely diffusible and exert their actions at a distance, but others are tethered to the cell surface and act locally. The second are surface receptors that enable cells to respond to inductive factors. Activation of these receptors triggers the expression of genes that encode intracellular proteins—transcription factors, enzymes, and cytoskeletal proteins—which push ectodermal cells along the pathway to becoming neural cells.

The ability of a cell to respond to inductive signals, termed its *competence*, depends on the exact repertory of receptors, transduction molecules, and transcription factors expressed by the recipient cell. Thus a cell's fate is determined not only by the signals to which it is exposed—a consequence of when and where it finds itself in the embryo—but also by the profile of genes it expresses as a consequence of its prior developmental history. We will see in subsequent chapters that the interaction of localized inductive signals and intrinsic cell responses is evident at virtually every step throughout neural development.

Development of the Neural Plate Is Induced by Signals from the Organizer Region

The discovery that specific signals are responsible for triggering the formation of the neural plate was the first major advance in understanding the mechanisms that pattern the nervous system. In 1924 Hans Spemann and Hilde Mangold made the remarkable observation that the differentiation of the neural plate from uncommitted ectoderm depends on signals secreted by a specialized group of cells they called the *organizer region*.

Working with amphibian embryos they showed that organizer activity is restricted to a region of the embryo called the dorsal lip of the blastopore, which is destined to form the dorsal mesoderm. Spemann and Mangold demonstrated the crucial role of the organizer

in forming the nervous system by transplanting small pieces of dorsal blastopore lip tissue underneath the ventral ectoderm of a host embryo, a region that normally gives rise to ventral epidermal tissue (Figure 52–3). By grafting organizer cells from a pigmented embryo into

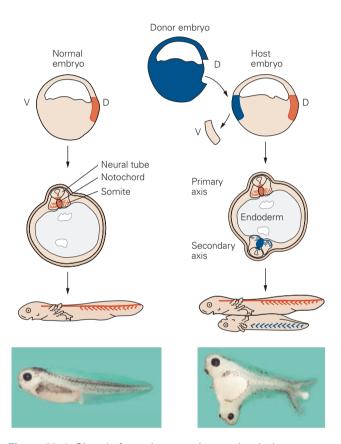

Figure 52–3 Signals from the organizer region induce a second neural tube. (Micrographs reproduced, with permission, from Eduardo de Robertis.)

Left: In the normal frog embryo cells from the organizer region (the dorsal blastopore lip) populate the notochord, floor plate, and somites. Right: Spemann and Mangold grafted the dorsal blastopore lip from an early gastrula stage embryo into a region of a host embryo that normally gives rise to the ventral epidermis. Signals from grafted cells induce a second embryonic axis, which includes a virtually complete neural tube. The donor tissue was from a pigmented embryo, whereas the host tissue was unpigmented, permitting the fate of grafted cells to be monitored by their characteristic pigmentation. Grafted cells themselves contribute only to the notochord, floor plate, and somites of the host embryo. As the embryo matures the secondary neural tube develops into a complete nervous system. In the Xenopus embryo shown in the micrograph, the second neural axis was induced by injection of an antagonist of bone morphogenetic protein (BMP), in effect substituting for the organizer signal (Figure 52-4). The primary neural axis is also apparent. (V, ventral; D, dorsal.)

an unpigmented host, they were able to distinguish the position and fate of donor and host cells.

Spemann and Mangold found that transplanted organizer cells followed their normal developmental program, generating midline mesoderm tissue such as the somites and notochord. But the transplanted cells also caused a striking change in the fate of the neighboring ventral ectodermal cells of the host embryo. Host ectodermal cells were induced to form a virtually complete copy of the nervous system (Figure 52–3). Spemann and Mangold went on to show that organizer cells were the only tissue that possessed this inductive effect.

These pioneering studies revealed that the nervous system is induced by signals from a highly restricted organizing center. As we will discuss, many aspects of neural tube patterning are now known to depend on signals secreted by other local organizing centers through actions similar in principle to that of the classical organizer region.

Neural Induction Is Mediated by Peptide Growth Factors and Their Inhibitors

For decades after Spemann and Mangold's pioneering studies, identification of the neural inducer constituted a Holy Grail of developmental biology. The search was marked by little success until the 1980s, when the advent of molecular biology and the availability of better markers of early neural tissue led to a breakthrough in our understanding of neural induction and its chemical mediators.

The first advance came from a simple finding: when the early ectoderm is dissociated into single isolated cells, effectively preventing cell-to-cell signaling, the cells readily acquire neural properties in the absence of added factors. The surprising implication of this finding was that the "default" fate of ectodermal cells is neural differentiation and that this fate is prevented by signals from neighboring ectodermal cells. In other words, the long sought-after "inducer" is actually a "de-repressor" of neural fate.

These ideas immediately raised two further questions. What ectodermal signal represses neural differentiation and what does organizer tissue provide to overcome the effects of the repressor? Studies of neural induction in frogs and chicks have now provided partial answers to these questions.

In the absence of signals from the organizer, ectodermal cells synthesize and secrete *bone morphogenetic proteins* (BMP), members of a large family of transforming growth factor β (TGF β) related proteins. The BMPs, acting through serine/threonine kinase class receptors on ectodermal cells, suppress the potential for neural differentiation and promote epidermal differentiation. Key evidence for the role of BMPs as neural repressors came from experiments in which a truncated version of a BMP receptor, which blocks BMP signaling, was found to trigger the differentiation of neural tissue in the *Xenopus* frog embryo. Conversely, exposure of ectodermal cells to BMP signaling promoted differentiation as epidermal cells (Figure 52–4).

The identification of BMPs as suppressors of neuronal differentiation in turn raised the possibility that the ability of organizer tissue to induce neural differentiation in ectodermal cells might be mediated by factors that antagonize BMP signaling. Direct support for this idea came from the finding that cells of the organizer region express many secreted proteins that act as BMP antagonists. These proteins include noggin, chordin, follistatin, and even some variant BMP proteins. Each of these proteins has the ability to induce ectodermal cells to differentiate into neural tissue. Thus there is no single neural inducer. In fact, multiple classes of proteins are required for induction, as shown by the later finding that the exposure of ectodermal cells to fibroblast growth factors (FGFs) is also a necessary step in neural differentiation.

Together these studies have provided a molecular explanation of the cellular phenomena first described by Spemann and Mangold. Nevertheless, many details of the pathway of neural induction remain to be clarified. We know that transcription factors of the SoxB family, expressed in prospective neural plate cells, function as intermediaries in the acquisition of neural character. But other components of the pathway remain to be uncovered.

Rostrocaudal Patterning of the Neural Tube Involves Signaling Gradients and Secondary Organizing Centers

As soon as cells of the neural plate have been induced they begin to acquire regional characteristics that mark the first steps in the differentiation of the forebrain, midbrain, hindbrain, and spinal cord. Cells in each of these four major regions acquire diverse neuronal fates and identities.

The subdivision of the neural plate into its major functional domains is directed by a series of secreted inductive factors and follows the same basic principles of neural induction. These inductive factors are initially secreted from mesodermal and endodermal cells that flank the neural plate. Later, after neural tube closure, they are also secreted from secondary organizing

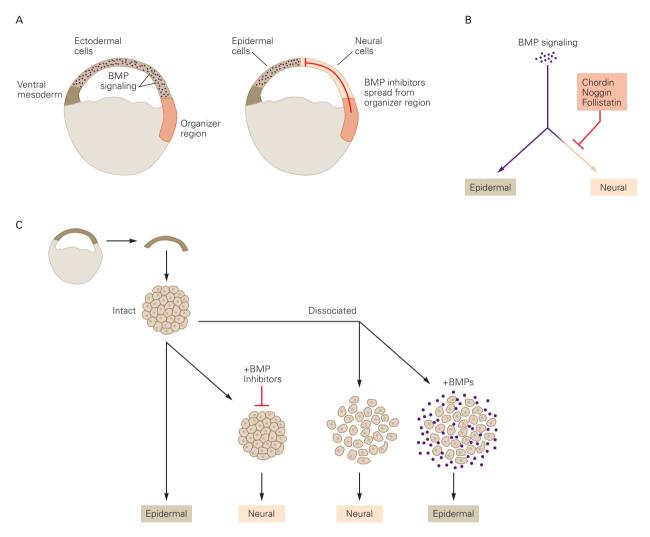

Figure 52–4 Inhibition of bone morphogenetic protein (BMP) signaling initiates neural induction.

A. In *Xenopus* frog embryos signals from the organizer region (**red line**) spread through the ectoderm to induce neural tissue. Ectodermal tissue that is beyond the range of organizer signals gives rise to epidermis.

B. BMP inhibitors secreted from the organizer region (including noggin, follistatin, and chordin) bind to BMPs and block the ability of ectodermal cells to acquire an epidermal fate, thus promoting neural character.

C. Ectodermal cells acquire neural or epidermal character depending on the presence or absence of BMP signaling. When ectodermal cell aggregates are exposed to BMP signaling they differentiate into epidermal tissue. When BMP signaling is blocked, either by dissociating ectodermal tissue into single cells or by addition of BMP inhibitors to ectodermal cell aggregates, the cells differentiate into neural tissue.

centers embedded within the neural tube. Some of these factors generate a broad rostrocaudal signaling gradient that can span the entire neural plate whereas others act more locally.

Neural plate cells in different regions of the neural tube respond to these inductive signals by expressing distinct transcription factors that gradually constrain the developmental potential of cells in each local domain. In this way neurons at different rostrocaudal levels acquire distinct identities and functions and the neural tube becomes subdivided along its rostrocaudal axis into functionally specific domains.

Signals from the Mesoderm and Endoderm Define the Rostrocaudal Pattern of the Neural Plate

The rostrocaudal patterning of the neural plate is initiated by factors secreted by mesodermal and endodermal

tissues that flank the neural plate. One important class of factors is the Wnt proteins (an acronym based on their founding family members, the *Drosophila Wingless* protein and the mammalian *Int1* proto-oncogene protein).

The net level of Wnt signaling activity is low at rostral levels of the neural plate and increases progressively in the caudal direction. This activity gradient arises because the mesoderm that flanks caudal regions of the neural plate expresses high levels of Wnt, whereas the endoderm that underlies the rostral region of the neural plate is a source of secreted proteins that inhibit Wnt signaling, much as BMP inhibitors attenuate BMP signaling at an earlier stage. Cells at progressively more caudal positions along the neural plate are exposed to increasing levels of Wnt activity and thus acquire a more caudal regional character, spanning the entire range from forebrain, to midbrain, to hindbrain and finally to spinal cord (Figure 52–5).

After the neural tube has acquired its initial rostrocaudal character, the mesoderm and endoderm secrete additional signals that further refine this pattern. At the very rostral margin of the neural tube a specialized group of cells, called the anterior neural ridge, secretes FGF that patterns the telencephalon, as we discuss later in the chapter. At more caudal levels of the neuraxis the secretion of retinoic acid and FGF from the mesoderm establishes distinct subdomains of the hindbrain and spinal cord.

Signals from Organizing Centers within the Neural Tube Pattern the Forebrain, Midbrain, and Hindbrain

The early influence of mesodermal and endodermal tissues on rostrocaudal neural pattern is further refined by signals from two specialized cell groups in the neural tube itself. One of these cell groups is called the *zona limitans intrathalamica* and appears as a pair of horn-like spurs within the diencephalon (Figure 52–6). Zona limitans intrathalamica cells secrete the protein sonic hedgehog (Shh), which patterns nearby cells that give rise to the nuclei of the thalamus. (The actions of sonic hedgehog are described in detail below in the context of its prominent role in spinal cord patterning.)

A second cell group, called the *isthmic organizer*, forms at the boundary of the hindbrain and midbrain. The isthmic organizer serves a key role in patterning these two domains of the neural tube as well as in specifying the neuronal subtypes within them. Dopaminergic neurons of the substantia nigra and ventral tegmental area are generated in the midbrain, just rostral to the isthmic organizer, whereas serotonergic

neurons of the raphe nuclei are generated just caudal to the isthmic organizer, within the hindbrain. As an illustration of how these secondary neural signaling centers impose neural pattern, we describe the origin and signaling activities of the isthmic organizer.

The rostrocaudal positional character of the neural plate stems from the expression of homeodomain transcription factors. Cells in forebrain and midbrain domains of the neural plate express Otx2, whereas cells in the hindbrain domain express Gbx2. The point of transition of Otx2 and Gbx2 expression is located at the midbrain-hindbrain boundary (Figure 52–5) and marks the position at which the isthmic organizer will emerge after neural tube closure. At this boundary other transcription factors are expressed, notably En1 (an Engrailed class transcription factor).

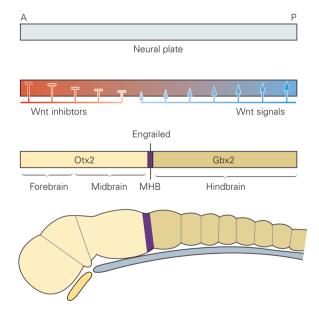

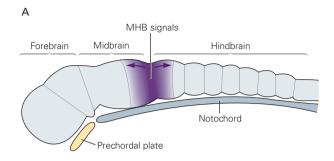

Figure 52–5 Early anteroposterior patterning signals establish distinct transcription factor domains and define the position of the midbrain-hindbrain boundary region. The anteroposterior pattern of the neural plate is established by exposure of neural cells to a gradient of Wnt signals. Anterior (A) regions of the neural plate are exposed to Wnt inhibitors secreted from the endoderm and thus perceive only low levels of Wnt activity. Progressively more posterior (P) regions of the neural plate are exposed to high levels of Wnt signaling from the paraxial mesoderm and to lower levels of Wnt inhibitors. In response to this Wnt signaling gradient and other signals, cells in anterior and posterior regions of the neural plate begin to express different transcription factors: Otx2 at anterior levels and Gbx2 at more posterior levels. The intersection of these two transcription factor domains marks the region of the midbrain-hindbrain boundary (MHB), where Engrailed transcription factors are expressed. (Adapted, with permission, from Wurst and Bally-Cuif 2001.)

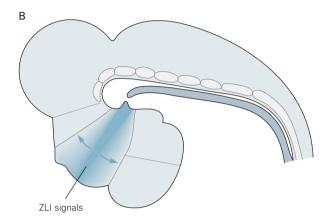

Figure 52–6 Local signaling centers in the developing neural tube. (Adapted, with permission, from Kiecker and Lumsden 2005)

A. This side view of the early neural tube shows the location of the midbrain-hindbrain boundary (MHB), the source of secreted signals that pattern cell types in the midbrain and hindbrain. The prechordal plate and notochord are two nonneural signaling centers that influence the dorsoventral patterning of the neural tube.

B. This side view of the neural tube at a later stage shows the position of the zona limitans intrathalamica (**ZLI**) at the boundary within the caudal forebrain (diencephalon). The ZLI is a source of sonic hedgehog signals.

These transcription factors in turn control the expression of two signaling factors, Wnt1 and FGF8, by cells of the isthmic organizer. Wnt1 is involved in the proliferation of cells in the midbrain-hindbrain domain and in the maintenance of FGF8 expression. The spread of FGF8 from the isthmic organizer into the midbrain domain marked by Otx2 expression induces differentiation of dopaminergic neurons, whereas its spread into the hindbrain domain marked by Gbx2 expression triggers the differentiation of serotonergic neurons (Figure 52–7A).

The differential action of FGF8 illustrates an important economy in early neural patterning. The

early actions of inductive signals impose discrete domains of transcription factor expression, and these transcriptional domains then allow cells to interpret the actions of the same secreted factor in different ways, producing different neuronal subtypes. In this way a relatively small number of secreted factors—FGFs, BMPs, hedgehog proteins, Wnt proteins, and retinoic acid—are used in different regions and at different times to program the vast diversity of neuronal cell types generated within the central and peripheral nervous systems.

Dorsoventral Patterning of the Neural Tube Involves Similar Mechanisms at Different Rostrocaudal Levels

As soon as the neural epithelium acquires its rostrocaudal character, cells located at different positions along its dorsoventral axis start to differentiate into various neuronal and glial cell types.

In contrast to the diversity of signals and organizing centers responsible for rostrocaudal patterning of developing neurons, there is a striking consistency in the strategies and principles that establish dorsoventral pattern. We focus initially on the mechanisms of dorsoventral patterning at caudal levels of the neural tube that give rise to the spinal cord, and then describe how similar strategies are used to pattern the forebrain.

Neurons in the spinal cord serve two major functions. They relay cutaneous sensory input to higher centers in the brain and they transform sensory input into motor output. The neuronal circuits that mediate these functions are segregated anatomically. Circuits involved in the processing of cutaneous sensory information are located in the dorsal half of the spinal cord, whereas those involved in the control of motor output are mainly located in the ventral half of the spinal cord. The neurons that form these circuits are generated at different positions along the dorsoventral axis of the spinal cord in a patterning process that begins with the establishment of distinct progenitor cell types.

In the ventral half of the neural tube motor neurons are generated close to the ventral midline, and most of the interneuron classes that control motor output are generated just dorsal to the position at which motor neurons appear (Figure 52–8). The dorsal half of the neural tube generates projection neurons and local circuit interneurons that process incoming sensory information. In addition, the dorsal neural tube gives rise to neural crest cells, a population of stem cells that migrate out of the neural tube into the periphery, where they serve as precursors to the entire peripheral nervous system.

How are the position and identity of spinal neurons established? The dorsoventral patterning of the neural tube is initiated by signals from mesodermal and ectodermal cells that lie close to the ventral and dorsal poles of the neural tube, and is perpetuated by signals from two midline neural organizing centers. Ventral patterning signals are initially provided by the notochord, a mesodermal cell group that lies immediately under the ventral neural tube, and this signaling activity is transferred to the floor plate, a specialized glial cell group that sits at the ventral midline of the neural tube itself. Dorsal signals are provided initially by cells of the epidermal ectoderm that span the dorsal midline of the neural tube, and subsequently by the roof plate, a glial cell group embedded at the dorsal midline of the neural tube (Figure 52-8D).

Thus neural patterning is initiated through a process of *homogenetic* induction, in which like begets like: Notochord signals induce the floor plate, which

induces ventral neurons, and signals from ectoderm induce the roof plate, which induces dorsal neurons. This strategy ensures that inductive signals are positioned appropriately to control neural cell fate and pattern over a prolonged period of development, as tissues grow and cells move.

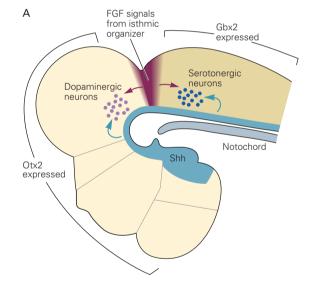

The Ventral Neural Tube Is Patterned by Sonic Hedgehog Protein Secreted from the Notochord and Floor Plate

Within the ventral half of the neural tube the identity and position of developing motor neurons and local interneurons depends on the inductive activity of the sonic hedgehog (Shh) protein, which is secreted by the notochord and subsequently by the floor plate (Figure 52–7A). Shh is a member of a family of secreted proteins related to the *Drosophila* hedgehog protein, which controls many aspects of embryonic development.

Figure 52–7 Signals from the midbrainhindbrain boundary pattern neurons in the midbrain and hindbrain.

A. Fibroblast growth factor (FGF) signals from the isthmic organizer act in concert with sonic hedgehog (Shh) signals from the ventral midline to specify the identity and position of dopaminergic and serotonergic neurons. The distinct fates of these two classes of neurons result from the different transcriptional profiles of cells in the midbrain (Otx2) and hindbrain (Gbx2). (Adapted, with permission, from Wurst and Bally-Cuif 2001.)

С

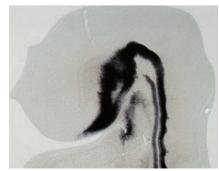

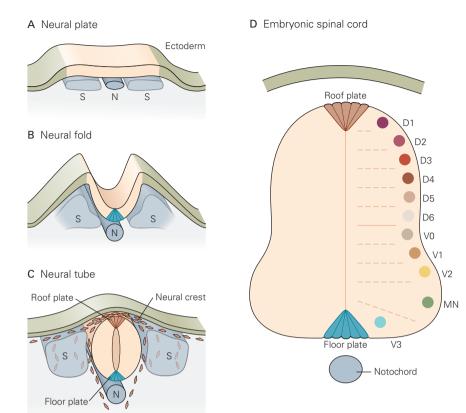

Figure 52–8 Stages in the early development of the spinal cord.

- A. The neural plate is generated from ectodermal cells that overlie the notochord (N) and the future somites (S). It is flanked by the epidermal ectoderm.
- **B.** The neural plate folds dorsally at its midline to form the neural fold. Floor plate cells (**blue**) differentiate at the ventral midline of the neural tube.
- C. The neural tube forms by fusion of the dorsal tips of the neural folds. Roof plate cells form at the dorsal midline of the neural tube. Neural crest cells migrate from the neural tube into and past the somites before populating the sensory and sympathetic ganglia.
- D. Distinct classes of neurons are generated at different dorsoventral positions in the embryonic spinal cord. Ventral interneurons (V0–V3) and motor neurons (MN) differentiate from progenitor domains in the ventral spinal cord. Six classes of early dorsal interneurons (D1 to D6) develop in the dorsal half of the spinal cord. (Adapted, with permission, from Goulding et al. 2002.)

Shh signaling is necessary for the induction of each of the neuronal classes generated in the ventral half of the spinal cord. How can a single inductive signal specify the fate of at least half a dozen neuronal classes? The answer lies in the ability of Shh to act as a morphogen—a signal that can direct different cell fates at different concentration thresholds. The secretion of Shh from the notochord and floor plate establishes a ventral-to-dorsal gradient of Shh protein activity in the ventral neural tube, such that progenitor cells that occupy different dorsoventral positions within the neural epithelium are exposed to small (two- to threefold) differences in ambient Shh signaling activity. Different levels of Shh signaling activity direct progenitor cells in different ventral domains to differentiation as motor neurons and interneurons (Figure 52-9).

These findings raise two additional questions. How is the spread of Shh protein within the ventral neural epithelium controlled in such a precise manner? And how are small differences in Shh signaling activity converted into all-or-none decisions about the identity of progenitor cells in the ventral neural tube?

Active Shh protein is synthesized from a larger precursor protein, cleaved through an unusual autocatalytic process that involves a serine protease-like activity resident within the carboxy terminus of the precursor protein. Cleavage generates an amino terminal protein fragment that possesses all of the signaling activity of Shh. During cleavage the active amino terminal fragment is modified covalently by the addition of a cholesterol molecule. The addition of this lipophilic anchor tethers most of the Shh protein to the surface of notochord and floor plate cells. Nevertheless, a small fraction of the anchored protein is released from the cell surface and transferred from cell to cell within the ventral neural epithelium. In reality the molecular machinery that ensures the formation of a long-distance gradient of extracellular Shh protein is more complex, involving specialized transmembrane proteins that promote the release of Shh from the floor plate, as well as proteins that regulate Shh protein transfer between cells.

How does the gradient of Shh protein within the ventral neural tube direct progenitor cells along different pathways of differentiation? Shh signaling is initiated by its interaction with a transmembrane receptor complex that consists of a ligand-binding subunit called *patched* and a signal-transducing subunit called *smoothened* (named for the corresponding fly genes).

The binding of Shh to patched relieves its inhibition of smoothened and so activates an intracellular signaling pathway that involves several protein kinase enzymes, transport proteins, and most important the Gli proteins, a class of zinc finger transcription factors.

In the absence of Shh the Gli proteins are proteolytically processed into transcriptional repressors that prevent the activation of Shh target genes. Activation of the Shh signaling pathway inhibits this proteolytic processing, with the result that transcriptional activator forms of Gli predominate, thus directing the expression of Shh target genes. In this way an extracellular gradient of Shh protein is converted into a nuclear gradient of Gli activator proteins. The ratio of Gli repressor and activator proteins at different dorsoventral positions determines which target genes are activated.

What genes are activated by Shh-Gli signaling and how do they participate in the specification of ventral neuronal subtypes? The major Gli targets are genes encoding yet more transcription factors. One major class of Gli targets encodes homeodomain proteins, transcription factors that contain a conserved DNA-binding motif termed a *homeobox*. A second major class of target genes encodes proteins with a basic helix-loop-helix DNA-binding motif. Some homeodomain and basic helix-loop-helix proteins are repressed and others activated by Shh signaling, each at a particular concentration threshold. In this way cells in the ventral neural tube are allocated to one of five cardinal progenitor domains, each marked by its own transcription factor profile (Figure 52–9).

The transcription factors that define adjacent progenitor domains repress each other's expression. Thus,

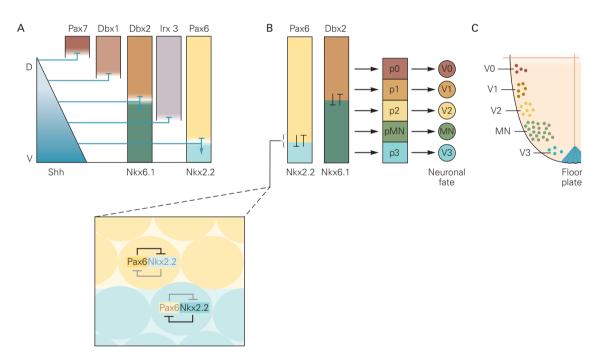

Figure 52–9 A sonic hedgehog signaling gradient controls neuronal identity and pattern in the ventral spinal cord.

A. A ventral-to-dorsal (V–D) gradient of sonic hedgehog (Shh) signaling establishes dorsoventral domains of homeodomain protein expression in progenitor cells within the ventral half of the neural tube. Graded Shh signaling generates a corresponding gradient of Gli transcription factor activity (not shown). At different concentrations the extracellular Shh and intracellular Gli gradients specify different neuronal classes. At each concentration a different homeodomain transcription factor (Pax7, Dbx1, Dbx2, Irx3, or Pax6) is repressed, with Pax7 the most sensitive and Pax6 the least sensitive to repression. Other homeodomain transcription factors (Nkx6.1 and Nkx2.2) are induced at different Shh and Gli signaling levels.

The homeodomain proteins that abut a common progenitor domain boundary have similar Shh concentration thresholds for repression and activation.

B. These transcription factors (Pax6 and Nkx2.2, Dbx2 and Nkx6.1 as examples) act in a cell-autonomous manner to repress each other's expression (inset), conferring cell identity to progenitor cells in an unambiguous manner. The sequential influence of graded Shh and Gli signaling, together with homeodomain transcriptional cross-repression, establishes five cardinal progenitor domains.

C. The postmitotic neurons that emerge from these domains give rise to the five major classes of ventral neurons: the interneurons V0–V3 and motor neurons (MN).

although a cell may initially express several transcription factors that could direct the cell along different pathways of differentiation, a minor imbalance in the starting concentration of the two factors is rapidly amplified through repression, and only one of these proteins is stably expressed. This winner-take-all strategy of transcriptional repression sharpens the boundaries of progenitor domains and ensures that an initial gradient of Shh and Gli activity will resolve itself into clear distinctions in transcription factor profile. The transcription factors that specify a ventral progenitor domain then direct the expression of downstream genes that commit progenitor cells to a particular postmitotic neuronal identity.

Studies of the logic of ventral neuronal patterning have thus shown that the fate of a neuron is determined in part by the actions of transcriptional repressors rather than activators. This principle operates in many other tissues and organisms, emphasizing that principles of neuronal patterning have been cobbled together from strategies that have proved useful in directing other aspects of embryonic development. Disruption of components of the Shh signaling pathway results in a wide variety of human diseases. Mutations in human Shh pathway genes result in defects in the development of ventral forebrain structures (holoprosencephaly), as well as neurological defects such as spina bifida, limb deformities, and certain cancers.

The Dorsal Neural Tube Is Patterned by Bone Morphogenetic Proteins

A signaling strategy based on graded morphogen levels activating sets of transcriptional programs has also been found to determine the patterning of cell types in the dorsal spinal cord. The differentiation of roof plate cells at the dorsal midline of the neural tube is triggered by BMP signals from epidermal cells that initially border the neural plate and later flank the dorsal neural tube.

After the neural tube has closed, roof plate cells themselves begin to express BMP as well as Wnt proteins. Wnt proteins promote the proliferation of progenitor cells in the dorsal neural tube. BMP proteins induce the differentiation of neural crest cells and later the generation of diverse populations of sensory relay neurons that settle in the dorsal spinal cord.

Dorsoventral Patterning Mechanisms Are Conserved Along the Rostrocaudal Extent of the Neural Tube

The strategies used to establish dorsoventral pattern in the spinal cord also control cell identity and pattern along the dorsoventral axis of the hindbrain and midbrain, as well as throughout much of the forebrain. In the mesencephalic region of the neural tube Shh signals from the floor plate act in concert with the rostrocaudal patterning signals discussed earlier to specify dopaminergic neurons of the substantia nigra and ventral tegmental area as well as serotonergic neurons of the raphe nuclei (see Figure 52–7). In the forebrain Shh signals from the ventral midline and BMP signals from the dorsal midline act in combination to establish different regional domains. Shh signaling from the ventral midline sets up early progenitor domains that later produce neurons of the basal ganglia and some cortical interneurons, whereas BMP signaling from the dorsal midline is involved in establishing early neocortical character.

Local Signals Determine Functional Subclasses of Neurons

To this point we have seen how a uniform group of neural precursor cells, the neural plate, is progressively partitioned into discrete rostrocaudal and dorsoventral domains within the neural tube, and how cells in these domains are subject to specialized programs of neural differentiation. But how are cells within these domains able to generate the extraordinary diversity of neuronal classes that typifies the vertebrate central nervous system? We answer that question by focusing on development of the motor neuron.

Motor neurons can be distinguished from all other classes of neurons in the central nervous system by the simple fact that they have axons that extend out of the spinal cord into the periphery. Viewed in this light, motor neurons represent a coherent and distinct subtype. But motor neuron subtypes can be distinguished by their position within the central nervous system as well as by the target cells they innervate. The primary job of most motor neurons is to innervate skeletal muscles, of which there are approximately 600 in a typical mammal. From this it follows that there must be an equal number of motor neuron classes.

In this section we discuss the developmental mechanisms that direct the differentiation of these different functional subclasses. The details of motor neuron development are also important for understanding the basis of neurological disorders that affect these neurons, including spinal muscular atrophy and amyotrophic lateral sclerosis (Lou Gehrig disease). Similar principles drive the diversification of other neuronal classes.

Rostrocaudal Position Is a Major Determinant of Motor Neuron Subtype

Motor neurons are generated along much of the rostrocaudal axis of the neural tube, from the midbrain to the spinal cord. Distinct motor neuron subclasses develop at each rostrocaudal level (Figure 52–10), suggesting that one goal of the patterning signals that establish rostrocaudal positional identity within the neural tube is to make motor neurons different.

One major class of genes involved in specifying motor neuron subtypes is the *Hox* gene family. These homeobox genes encode a family of transcription factors that contain a homeodomain. Homeodomain

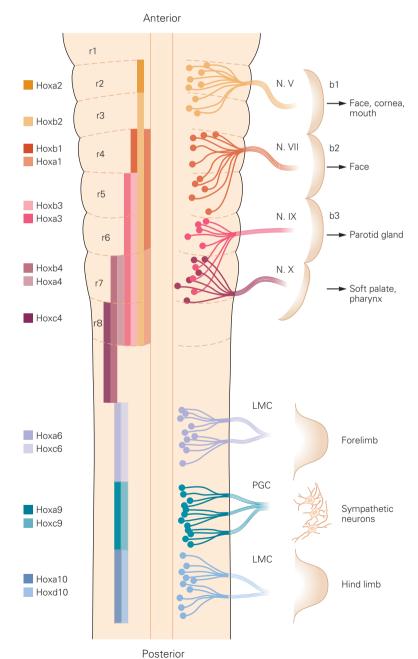

proteins represent a major class of transcription factors that regulate developmental processes in organisms as diverse as yeast, plants, and mammals. The mammalian genome contains 39 *Hox* genes, organized in four chromosomal clusters. These genes derive from an ancestral *Hox* complex that also gave rise to the *HOM-C* gene complex in *Drosophila* (Figure 52–11).

Members of the vertebrate *Hox* gene family are expressed in overlapping domains along the rostrocaudal

Figure 52–10 The anteroposterior profile of *Hox* gene expression determines the subtype of motor neurons in the hindbrain and spinal cord. Different Hox proteins are expressed in discrete but partially overlapping rostrocaudal domains of the hindbrain and spinal cord. The position of *Hox* genes on the four mammalian chromosomal clusters roughly corresponds to their domain of expression along the anteroposterior axis of the neural tube.

At hindbrain levels motor neurons sending axons into cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus) are depicted. These cranial motor nerves project to peripheral targets in the branchial arches b1-b3. The hindbrain rhombomeres (r1-r8) and Hox profiles are shown on the left.

At spinal levels, motor neurons that send axons to the forelimb and hind limb are contained within the lateral motor columns (LMC), located at brachial and lumbar levels of the spinal cord, respectively. Preganglionic autonomic motor neurons (PGC) destined to innervate sympathetic ganglion targets are generated at thoracic levels. (Adapted, with permission, from Kiecker and Lumsden 2005.)

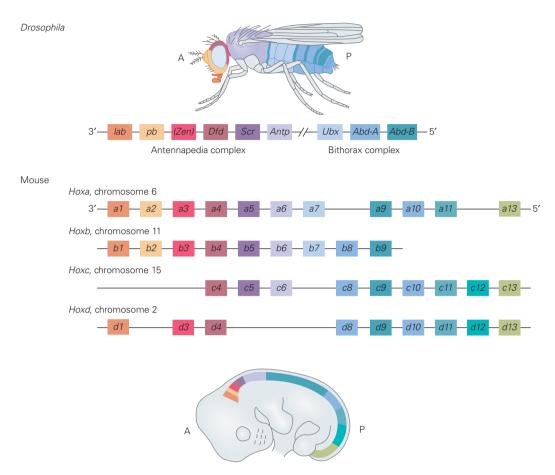

Figure 52–11 The clustered organization of *Hox* genes is conserved from flies to vertebrates. The diagram shows the chromosomal arrangement of *Hox* genes in the mouse and *HOM-C* genes in *Drosophila*. Insects have one ancestral *Hox* gene cluster, whereas higher vertebrates such as birds and

mammals have four duplicate *Hox* gene clusters. The position of a given *Hox* or *HOM-C* gene on the chromosomal cluster is typically related to the position on the anteroposterior body axis where the gene is expressed. (Adapted, with permission, from Wolpert et al. 1988.)

axis of the developing midbrain, hindbrain, and spinal cord. As in *Drosophila*, the position of an individual *Hox* gene within its cluster predicts its rostrocaudal domain of expression within the neural tube. In most but not all cases, *Hox* genes located at more 3' positions within the chromosomal cluster are expressed in more rostral domains, within the midbrain and hindbrain, whereas genes at more 5' positions are expressed in progressively more caudal positions within the spinal cord (Figures 52–10 and 52–11). This spatial array of *Hox* gene expression determines many aspects of motor neuron subtype.

We illustrate how *Hox* genes control motor neuron identity by focusing on neurons generated in the hindbrain and spinal cord. The fundamental cellular building blocks of the hindbrain are termed *rhombomeres*, compartmental units that are arrayed along

the rostrocaudal axis of the hindbrain (Figure 52–10). Genetic studies in the mouse have shown that specific *Hox* genes control the identity of neurons in individual rhombomeres. For example, *Hoxb1* is expressed at high levels in rhombomere 4, the domain that gives rise to facial motor neurons, but is absent from rhombomere 2, the domain that gives rise to trigeminal motor neurons (Figure 52–10).

In the mouse, mutations that eliminate the activity of *Hoxb1* change the fate of cells in rhombomere 4; there is a switch in the identity and connectivity of the motor neurons that emerge from this domain. In the absence of *Hoxb1* function cells in rhombomere 4 generate motor neurons that innervate trigeminal rather than facial targets, that is, the motor neuron subtype normally generated within rhombomere 2 (Figure 52–12).

Other studies of *Hox* gene function within the hindbrain have confirmed the general principle that motor neuron identity is controlled by the spatial distribution of *Hox* gene expression.

The challenge of connecting individual spinal motor neurons with particular muscles in the limbs and body wall demands an even more complex program of cellular and molecular differentiation. Spinal motor neurons are clustered within longitudinal columns that occupy discrete segmental positions, in register with their peripheral targets. Motor neurons that innervate forelimb and hindlimb muscles are found in the lateral motor columns at cervical and lumbar levels of the spinal cord, respectively. In contrast, motor neurons that innervate sympathetic neuronal targets are found within the preganglionic motor column at thoracic levels of the spinal cord. Within the lateral motor columns, motor neurons that innervate a single limb muscle are clustered together into discrete groups, termed motor pools. Because each limb in higher vertebrates contains more than 50 different muscle groups, a corresponding number of motor pools are required.

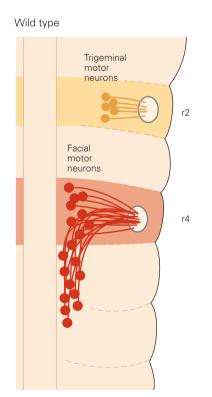

The identity of motor neurons in the spinal cord is controlled by the coordinate activity of *Hox* genes found at more 5' positions within the chromosomal

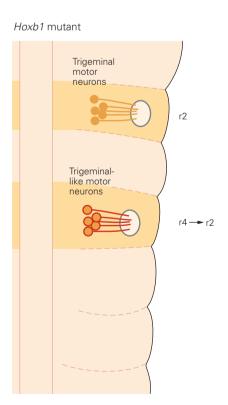

Hox clusters. For example, the spatial domains of expression and activity of Hox6 and Hox9 proteins establish the identities of motor neurons in the brachial lateral motor column and the preganglionic motor column. Hox6 proteins specify brachial lateral motor column identity, whereas Hox9 proteins specify preganglionic motor column identity. Motor neurons at the boundary of the forelimb and thoracic regions acquire an unambiguous columnar identity because the Hox6 and Hox9 proteins are mutually repressive (Figure 52–13), similar to the transcriptional cross-repression that occurs in the dorsoventral patterning of the spinal cord.

Local Signals and Transcriptional Circuits Further Diversify Motor Neuron Subtypes

How do motor neurons within the lateral motor columns develop more refined identities, directing their axons to specific limb muscles? Once again, *Hox* genes control this stage of motor neuron diversification. We illustrate this function of Hox proteins by considering the pathway that generates the distinct divisional and pool identities of neurons within the brachial lateral motor column that innervate the muscles of the forelimb (Figure 52–13A).

Figure 52–12 The mouse Hoxb1 gene controls the identity and projection of hindbrain motor neurons. Hoxb1 is normally expressed at highest levels by cells in rhombomere r4. In wild type mice trigeminal motor neurons are generated in rhombomere r2, and their cell bodies migrate laterally before projecting their axons out of the hindbrain at the r2 level. In contrast, the cell bodies of facial motor neurons generated in rhombomere r4 migrate caudally yet project their axons out of the hindbrain at the r4 level. In mouse Hoxb1 mutants motor neurons generated in rhombomere r4 migrate laterally instead of caudally, acquiring the features of r2 level trigeminal motor neurons. Ellipses indicate axonal exit points. (Adapted, with permission, from Struder et al. 1996.)

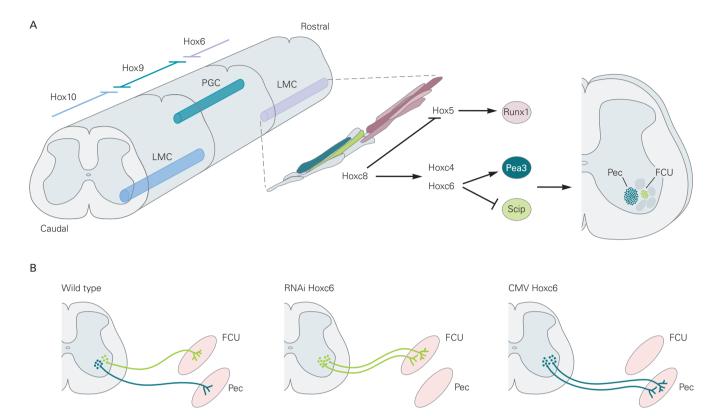

Figure 52–13 Hox proteins control the identity of neurons in motor columns and pools. (Adapted, with permission, from Daser et al. 2005.)

A. Hox6, Hox9, and Hox10 proteins are expressed in motor neurons at distinct rostrocaudal levels of the spinal cord and direct motor neuron identity and peripheral target connectivity. Hox6 activities control the identity of cells in the brachial lateral motor column (LMC), Hox9 controls the identity of cells in the preganglionic column (PGC), and Hox10 the identity of cells in the lumbar column (LMC). Cross-repressive interactions between Hox6, Hox9, and Hox10 proteins refine Hox profiles, and Hox activator functions define LMC and PGC identities. A more complex Hox transcriptional network controls motor pool identity and connectivity. Hox genes determine the rostrocaudal position of motor pools within the LMC. Hoxc8 is required in caudal LMC

neurons to generate the motor pools for the pectoralis (**Pec**) and flexor carpi ulnaris (**FCU**) muscles; these neurons express the transcription factors Pea3 and Scip, respectively. The patterns of Hox expression in the Pec and FCU pools are established through a transcriptional network that appears to be driven largely by Hox cross-repressive interactions.

B. Changing the Hox code within motor pools changes the pattern of muscle connectivity. Alterations in the profile of Hox6 expression determine the expression of Pea3 and Scip and control the projection of motor axons to the Pec or FCU muscles. RNAi knock-down of Hox6 suppresses innervation of the Pec muscle so that motor axons innervate the FCU muscle only. Ectopic expression of Hox66 driven by a cytomegalovirus (CMV) promoter represses connectivity with FCU, so that motor axons innervate only the Pec muscle.

Additional repressive interactions between Hox proteins expressed by the neurons in different lateral motor columns ensure that neurons that populate different motor pools express distinct profiles of Hox protein expression. These Hox profiles direct the expression of downstream transcription factors as well as the axonal surface receptors that enable motor axons to respond to local cues within the limb that guide them to specific muscle targets (Figure 52–13A).

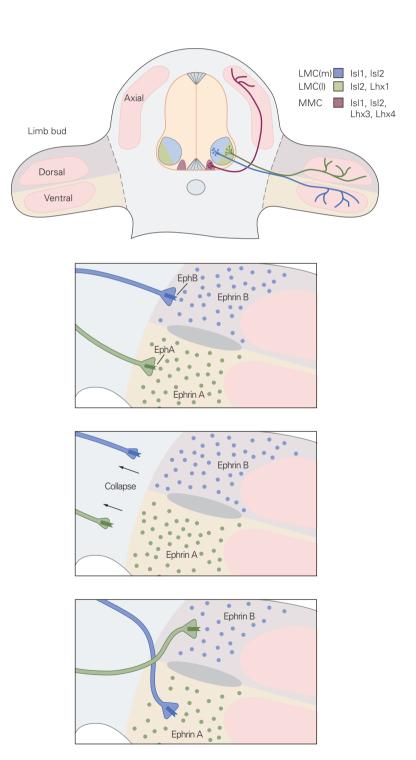

Hox proteins control the expression of receptors for guidance cues that direct motor axons into the limb.

The expression of Hox6 proteins activates a retinoic acid signaling pathway that directs the expression of two homeodomain transcription factors, Is11 and Lhx1. These factors in turn assign motor neurons into two divisional classes and determine the pattern of expression of the ephrin receptors that guide motor axons in the limb. The axons of motor neurons in these two divisions project into the ventral and dorsal halves of the limb mesenchyme under the control of ephrin signaling (Figure 52–14). The mechanism by which ephrins direct axons along specific trajectories will be described in Chapter 54.

Not all motor neuron columns are determined by Hox protein activity, however. The median motor column is generated at all segmental levels of the spinal cord in register with axial muscles. Development of median motor column cells is controlled by Wnt4/5

signals secreted from the ventral midline of the spinal cord, and by the expression of the homeodomain proteins Lhx3 and Lhx4, which render neurons in this column immune to the segmental patterning actions of Hox proteins.

Figure 52-14 The axons of lateral motor column neurons are guided into the limb by ephrin class tyrosine kinase receptors. Motor neurons in the medial and lateral divisions of the lateral motor column (LMC) project axons into the ventral and dorsal halves of the limb mesenchyme, respectively. The profile of expression of LIM class homeodomain proteins regulates this dorsoventral projection. The LIM homeodomain protein Isl1 expressed by medial LMC neurons directs a high level of expression of EphB receptors, such that as the axons of these cells enter the limb they are prevented from projecting dorsally by the high level of repellant ephrin B ligands expressed by cells of the dorsal limb mesenchyme. These axons therefore project into the ventral limb mesenchyme. Conversely, the LIM homeodomain protein Lhx1 expressed by lateral LMC neurons directs a high level of expression of EphA receptors, such that as the axons of these cells enter the limb they are prevented from projecting ventrally by the high level of repellant ephrin A ligands expressed by cells of the ventral limb mesenchyme. These axons therefore project into the dorsal limb mesenchyme. (MMC, medial motor column.)

Thus in both the hindbrain and spinal cord the point-to-point connectivity of motor neurons with specific muscles emerges through tightly orchestrated programs of homeodomain protein expression and activity. In vertebrates these genes have evolved to direct neuron subtype and connectivity as well the basic body plan.

The Developing Forebrain Is Patterned by Intrinsic and Extrinsic Influences

Neurons in the mammalian forebrain form circuits that mediate emotional behaviors, perception, and cognition and participate in the storage and retrieval of memories. Much like the hindbrain, the embryonic forebrain is initially divided along its rostrocaudal axis into transversely organized domains called *prosomeres*. Prosomeres 1 to 3 develop into the caudal part of the diencephalon, from which the thalamus emerges. Prosomeres 4 to 6 give rise to the rostral diencephalon and telencephalon. The ventral region of the rostral diencephalon gives rise to the hypothalamus and basal ganglia, whereas the telencephalon gives rise to the neocortex and hippocampus.

We have described how signals establish dorsoventral domains of the forebrain that later give rise to the hypothalamus, the basal ganglia, and the telencephalon. Here we turn to the patterning of the neocortex itself, asking whether the developmental mechanisms and principles that govern the development of other regions of the central nervous system also control the emergence of cortical areas specialized for particular sensory, motor, and cognitive functions.

Inductive Signals and Transcription Factor Gradients Establish Regional Differentiation

From the time of Brodmann's classical anatomical description at the beginning of the 20th century we have known that the cerebral cortex is subdivided into many different functional areas. Recent studies of cortical development have begun to provide insight into the signaling mechanisms that establish these basic subdivisions, forming somatosensory, auditory, and visual areas.

There is now evidence for the existence of a cortical "protomap," a basic plan in which different cortical areas are established early in development before inputs from other brain regions can influence development. This view is supported by studies of transcription factor expression in the developing neocortex. Two homeodomain transcription factors, Pax6 and

Emx2, are expressed in complementary anteroposterior gradients in the ventricular zone of the developing neocortex—high levels of Pax6 at anterior levels and high levels of Emx2 at posterior levels. These early patterns are established in part by a local rostral source of FGF signals, which promote Pax6 and repress Emx2 expression (Figure 52–15A).

The distinct spatial domains of expression of Pax6 and Emx2 also depend on cross-repressive interactions between the two transcription factors. The spatial distribution of Pax6 and Emx2 helps to establish the initial regional pattern of the neocortex. In mice lacking Emx2 activity there is an expansion of rostral neocortex—the motor and somatosensory areas—at the expense of the more caudal auditory and visual areas. Conversely, in mice lacking Pax6 activity visual and auditory areas are expanded at the expense of motor and somatosensory areas (Figure 52–15B).

Thus, as in the spinal cord, hindbrain, and midbrain, early neocortical patterns are established through the interplay between local inductive signals and gradients of transcription factor expression. How these gradients specify discrete functional areas in the neocortex remains unclear. Transcription factors that precisely mark individual neocortical areas early in development have not yet been identified, although surface adhesion proteins, such as the cadherins, are known to segregate to specific sensory and motor areas.

Afferent Inputs Also Contribute to Regionalization

In the adult neocortex different functional areas can be distinguished by differences in the layering pattern of neurons—the cytoarchitecture of the areas—and by their neuronal connections. One striking instance of regional distinctiveness in cell pattern is a grid-like array of neurons and glial cells termed "barrels" in the primary somatosensory cortex of rodents. Each cortical barrel receives somatosensory information from a single whisker on the snout of the animal, and the regular array of cortical barrels reflects the somatotopic organization of afferent information from the body surface, culminating in the projection of thalamic afferents to specific cortical barrels (Figure 52–16A).

Cortical barrels are evident soon after birth, and their development depends on a critical period of afferent input from the periphery; their formation is disrupted if the whisker field in the skin is eliminated during this critical period. Strikingly, if prospective visual cortical tissue is transplanted into the somatosensory cortex around the time of birth, barrels form in the transplanted tissue with a pattern that closely

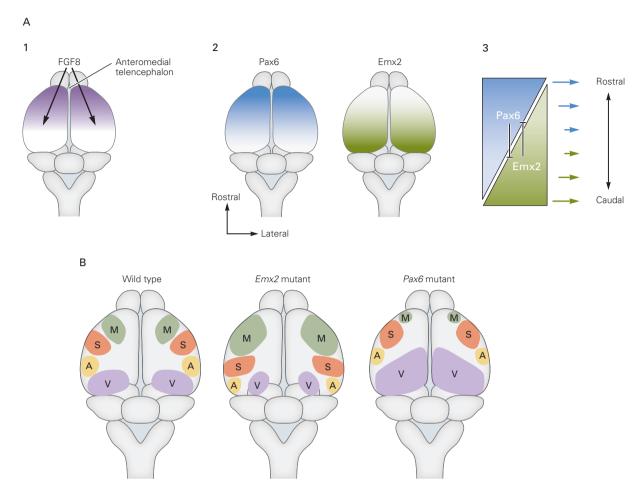

Figure 52–15 Anteroposterior gradients of expression of transcription factors establish discrete functional areas along the anteroposterior axis of the developing forebrain. (Adapted, with permission, from Hamasaki et al. 2004.)

A. (1) FGF8 signals from the anteromedial telencephalon establish the rostrocaudal pattern of the cerebral cortex. (2) A top-down view of the developing cerebral cortex in the mouse shows inverse rostrocaudal gradients of the transcription factors Pax6 and Emx2. (3) These two transcription factors mutually repress each other's expression.

B. Different functional areas develop at different rostrocaudal positions. Motor areas develop in the anterior region (**M**) and visual areas in more posterior regions (**V**). Genetic elimination of Emx2 function results in expansion of the motor areas and contraction in auditory (**A**) and visual areas. Conversely, elimination of Pax6 function results in an expansion of the visual areas and a contraction of motor and auditory areas. (**S**, somatosensory areas.)

resembles that of the normal somatosensory barrel field (Figure 52–16B). Together these findings demonstrate that afferent input superimposes aspects of neocortical patterning on the basic features of the protomap.

The nature of the input to different cortical areas influences neural function as well as cytoarchitecture. This can be shown by monitoring physiological and behavioral responses after rerouting afferent pathways of one sensory modality to a region of neocortex that normally processes a different modality. In animals in which retinal inputs are rerouted into the auditory

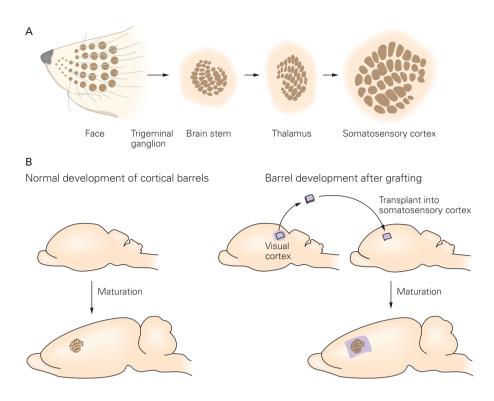

pathway, the primary auditory cortex contains a systematic representation of visual space rather than of sound frequency (Figure 52–17). When these animals are trained to discriminate a visual from an auditory cue, they perceive a cue as visual when the rewired auditory cortex is activated by vision.

Thus brain pathways and neocortical regions are established through genetic programs during early development but later depend on afferent inputs for their specialized anatomical, physiological, and behavioral functions.

Figure 52–16 Sensory input regulates the organization of "barrels" in the developing somatosensory cortex in rodents. (Adapted, with permission, from Schlagger and O'Leary 1991.)

A. The barrel area of the rodent somatosensory cortex forms a somatotopic representation of the rows of whiskers on the animal's snout. Similar representations of the whisker field are present upstream—in the brain stem and in the thalamic nuclei that relay somatosensory inputs from the face to the cortex.

B. A barrel-like cellular organization is induced in developing visual cortex tissue that was grafted at an early postnatal stage into the somatosensory cortex.

A Reorganization of thalamic pathways **B** Orientation maps Normal Visual Inferior Auditory cortex (V1) colliculus cortex (A1) Normal V1 LGŃ MGN Retina Cochlea Rewired Visually responsive Ablated auditory cortex Rewired A1 Retina

Figure 52–17 Rerouting thalamocortical input can recruit cortical areas for new sensory functions. (Adapted from Sharma, Angelucci, and Sur 2000.)

A. The visual pathway consists of afferent fibers from the retina that innervate the lateral geniculate nucleus (LGN) and superior colliculus. Axons from the LGN project to the primary visual cortex (V1). The auditory pathway projects from the cochlear nucleus (not shown) to the inferior colliculus, and then to the medial geniculate nucleus (MGN) and on to the primary

auditory cortex (A1). Ablating the inferior colliculus in neonatal ferrets causes retinal afferents to innervate the MGN. As a consequence, the auditory cortex is reprogrammed to process visual information.

B. Visual orientation maps similar to those seen in normal V1 cortex are observed in rewired A1 auditory cortex of ferrets using optical imaging of intrinsic signals. The different colors represent different receptor field orientations (see bars at right). The pattern of activity in rewired A1 resembles that of normal V1.

An Overall View

The diverse functions of the mature vertebrate nervous system arise from regionally distinct subdivisions of the neural tube. Establishment of these subdivisions proceeds in four major developmental steps: (1) the generation of progenitor cells in the neural plate and neural tube, (2) the generation of regional differences within the neural tube that correspond to the major subdivisions of the mature nervous system, (3) the specification of distinct neuronal subtypes, and (4) the influence of neuronal inputs.

The early pattern of cell differentiation in the neural tube can be viewed as a series of inductive interactions in which signals provided by one cell group direct the fate of neighboring cells. The extensive diversification of cell types is orchestrated by a surprisingly small number of inducing factors that control programs of transcription factor expression in target cells. The developmental history of the cell, as well as the profile of transcription factors it expresses at a given time in development, determines its responsiveness to these inducing factors.

Despite differences in the organization of the nervous systems of invertebrates and vertebrates, the signaling molecules responsible for the differentiation and patterning of developing neurons have been conserved throughout animal evolution to a surprisingly high degree, reflecting an economical use of genetic information. Not only are the same signaling molecules used in many different organisms, but the receptors for these signals and the developmental programs they activate are also conserved. In addition, the same signals are used at many different developmental stages within one organism. Thus, the analysis of the development of the vertebrate nervous system has benefited greatly from genetic studies of flies and worms.

An Overall View

In the preceding chapter we described how local inductive signals pattern the neural tube and establish the early regional subdivisions of the nervous system—the spinal cord, hindbrain, midbrain, and forebrain. Here we turn to the issue of how progenitor cells within these regions differentiate into neurons and glial cells, the two major cell types that populate the nervous system.

We discuss some of the molecules that specify neuronal and glial cell fates and how they are regulated. The basic mechanisms of neurogenesis endow cells with common neuronal properties, features that are largely independent of the region of the nervous system in which they are generated or the specific functions they perform. We also discuss the mechanisms by which developing neurons express neurotransmitters and synaptic receptors.

After the identity and functional properties of the neuron have begun to emerge, additional developmental processes determine whether the neuron will live or die. Remarkably, approximately half of the neurons generated in the mammalian nervous system are lost through programmed cell death. We examine the factors that regulate the survival of neurons and the possible benefits of widespread neuronal loss. Finally, we describe the existence of a core biochemical pathway that programs the death of nerve cells.

The Proliferation of Neural Progenitor Cells Involves Symmetric and Asymmetric Modes of Cell Division

The mature brain comprises billions of nerve cells and even more glial cells. Yet its precursor, the neural plate, initially comprises only a few hundred cells. From this simple comparison we infer that regulation of the proliferation of neural cells is a major driving force in shaping brain development. Histologists in the late 19th century showed that neural epithelial cells close to the ventricular lumen of the embryonic brain exhibit features of mitosis, and we now know that the proliferative zones surrounding the ventricles are the major regions involved in the production of neural cells in the cerebral cortex as well as other regions of the central nervous system.

At early stages of embryonic development most progenitor cells in the ventricular zone of the neural tube proliferate rapidly. Many of these early neural progenitors have the properties of stem cells: They can generate additional copies of themselves, a process called *self-renewal*, and also give rise to differentiated neurons and glial cells (Figure 53–1B). As with other types of stem cells, neural progenitor cells undergo stereotyped programs of cell division.

One mode of cell division is asymmetric: The progenitor produces one differentiated daughter and another daughter that retains its stem cell-like properties. This mode does not permit amplification of the stem cell population. In a second mode neural stem cells divide symmetrically to produce two stem cells, and in this way expand the population of proliferative progenitor cells. Both symmetric and asymmetric modes have been found in the embryonic cerebral cortex in vivo and in cortical cells grown in tissue culture (Figure 53–1C).

The incidence of symmetric and asymmetric cell division is influenced by signals in the local environment of the dividing cell, making it possible to control the probability of self-renewal or differentiation. Environmental factors can influence the outcome of progenitor cell divisions in two fundamental ways. They can act in an "instructive" manner, biasing the outcome of the division process and causing the stem cell to adopt one fate at the expense of others. Or they can act in a "selective" manner, permitting the survival and maturation of only certain cell progeny.

Radial Glial Cells Serve As Neural Progenitors and Structural Scaffolds

Radial glial cells are the earliest morphologically distinguishable cell type to appear within the primitive neural epithelium. Their cell bodies are located in the ventricular zone and their long process extends to the pial surface. As the brain thickens, the processes of radial glial cells remain attached to the ventricular and pial surfaces. After the generation of neurons is complete,

many radial glial cells differentiate into astrocytes, a prominent class of glial cell in the mature brain. The elongated shape of the radial glial cell places it in a favorable position to serve as a scaffold for the migration of neurons that emerge from the ventricular zone (Figure 53–2).

The ventricular zone was once thought to contain two major cell types: radial glial cells and a set of neuroepithelial progenitors, which served as the primary source of neurons. This classical view has changed dramatically in the last few years. Radial glial cells are in fact progenitor cells that generate both neurons and astrocytes in addition to their role in neuronal migration (Figure 53-2). When radial glial cells are selectively labeled with fluorescent dyes or viruses, tracing of their clonal progeny reveals cell clusters that contain both neuronal and radial glial cells. These findings indicate that radial glial cells are able to undergo both asymmetric and self-renewing cell division, and serve as a major source of post-mitotic neurons as well as astrocytes. Radial glial cells may also serve as progenitors of neurons in the adult central nervous system.

The Generation of Neurons or Glial Cells Is Regulated by Delta-Notch Signaling and Basic Helix-Loop-Helix Transcription Factors

How do radial glial cells make the decision to selfrenew, generate neurons, or give rise to mature astrocytes? The answer to this question involves an evolutionarily conserved signaling system.

In flies and vertebrates neural fate is regulated by a cell-surface signaling system, comprised of the transmembrane ligand delta and its receptor notch, which regulates a cascade of transcription factors of the basic helix-loop-helix (bHLH) family. This signaling system was revealed in genetic studies in *Drosophila*. Neurons emerge from within a larger cluster of ectodermal cells, each of which has the potential to generate neurons. This *proneural region* is defined by expression of proneural genes, which encode transcription factors of the bHLH class. Yet within the proneural region only certain cells form neurons; the others become epidermal support cells.

Initially the ligand delta and its receptor notch are expressed at similar levels by all proneural cells (Figure 53–3A). With time, however, notch activity is enhanced in one cell and suppressed in its neighbor. The cell in which notch activity is highest loses the potential to form a neuron and acquires an alternative fate.

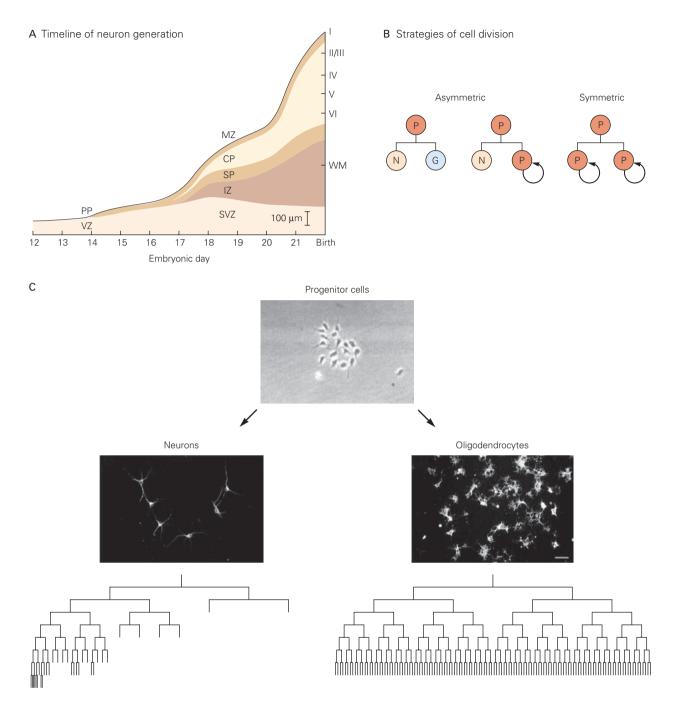

Figure 53–1 Neural progenitor cells have different modes of division.

A. Temporal sequence of neurogenesis in the mouse cerebral cortex. Neurons begin to accumulate in the cortical plate (CP) during the last 5 days of embryonic development. Within the cortical plate neurons populate the deep layers before settling in the superficial layers. (MZ, marginal zone; PP, preplate; SP, subplate; IZ, intermediate zone; SVZ, subventricular zone; VZ, ventricular zone; WM, white matter.)

B. Asymmetric and symmetric modes of cell division. A progenitor cell (P) undergoes asymmetric division to generate a neuron (N) and a glial cell (G) (left). A progenitor cell undergoes asymmetric division, giving rise to another progenitor cell and a neuron. This mode of division contributes to the generation of neurons at early stages of development, and of glial cells at later stages, typical of many regions of the central nervous system (middle). A progenitor cell undergoes symmetric division to generate two additional progenitor cells (right).

C. Time-lapse cinematography captures the divisions and differentiation of isolated cortical progenitor cells in the rodent. Lineage diagrams illustrate cells that undergo predominantly asymmetric division, giving rise to neurons (left), or symmetric division that gives rise to oligodendrocytes (right). (Modified, with permission, from Qian et al. 1998.)

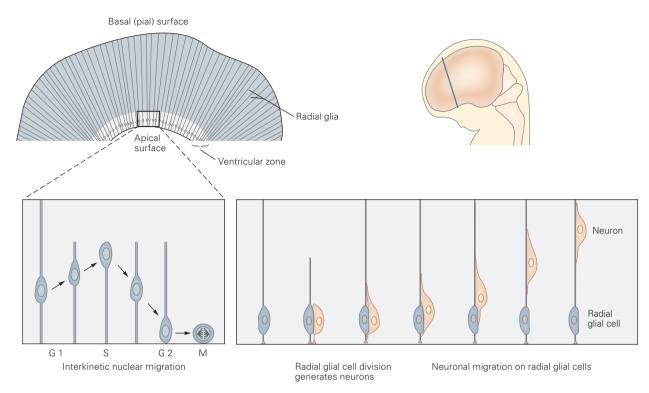

Figure 53–2 Radial glial cells serve as precursors to neurons in the central nervous system and also provide a scaffold for radial neuronal migration. Progenitor cells in the ventricular zone of the developing cerebral cortex have nuclei that migrate along the apical-basal axis as they progress through the cell cycle. Left: During the G1 phase nuclei rise from the inner (apical) surface of the ventricular zone. During

the S phase they reside in the outer (basal) third of the ventricular zone. During the G2 phase they migrate apically, and mitosis occurs when the nuclei reach the ventricular surface. **Right**: During cell division radial glial cells give rise to postmitotic neurons that migrate away from the ventricular zone using radial glial cells as a guide.

The binding of Delta to Notch results in proteolytic cleavage of the Notch cytoplasmic domain, which then enters the nucleus. There it functions as a transcription factor, regulating the activity of bHLH transcription factors that suppress the ability of the cell to become a neuron and reduce the level of expression of the ligand Delta (Figure 53–3B). Through this feedback pathway a minor difference in the initial level of Notch signaling is rapidly amplified to generate an all-or-none difference in the status of Notch activation, and consequently the fates of the two cells. This basic logic of Delta-Notch and bHLH signaling has been conserved in vertebrate and invertebrate neural tissues.

How does Notch signaling regulate neuronal and glial production in mammals? At early stages in the development of the mammalian cortex Notch signaling promotes the generation of radial glial cells by activating members of the Hes family of bHLH transcriptional repressors. Two of these proteins, Hes1 and

Hes5, appear to maintain radial glial cell character by activating the expression of an ErbB class tyrosine kinase receptor for neuregulin, a secreted signal that promotes radial glial cell identity. The Notch ligand Delta1 as well as neuregulin are expressed by newly generated cortical neurons; thus the radial glial cells depend on feedback signals from their neuronal progeny for continued production.

At later stages of cortical development Notch signaling continues to activate Hes proteins, but a change in the intracellular response pathway results in astrocyte differentiation. At this stage the Hes proteins work by activating a transcription factor, STAT3, which recruits the serine-threonine kinase JAK2, a potent inducer of astrocyte differentiation. STAT3 also activates expression of astrocyte-specific genes such as the glial-fibrillary acidic protein (GFAP).

The generation of oligodendrocytes, the second major class of glial cells in the central nervous system, follows many of the principles that control neuron and astrocyte production. Notch signaling regulates the expression of two bHLH transcription factors, Olig1 and Olig2, which have essential roles in the production of embryonic and postnatal oligodendrocytes.

The generation of cortical neurons requires that cells avoid exposure to notch signals (Figure 53–4). This

task is achieved in part through the expression of numb, a cytoplasmic protein that antagonizes notch signaling. The key role of numb in neurogenesis was first shown in *Drosophila*, where it determines the neuronal fate of daughter cells of asymmetrically dividing progenitors. In the mammalian cortex numb, as with Notch,

Figure 53–3 Delta acts as a ligand for Notch and determines neuronal fate.

A. At the onset of the interaction between two cells, the ligand Delta engages the receptor Notch. Delta and Notch are expressed at similar levels on each cell, and thus their initial signaling strength is equal.

B. A small imbalance in the strength of Delta-Notch signaling breaks the symmetry of the interaction. In this example the left cell provides a slightly greater Delta signal, thus activating Notch signaling in the right cell to a greater extent. On binding by Delta, the cytoplasmic domain of Notch is cleaved to form a proteolytic fragment called Notch-Intra, which enters the nucleus of the cell and initiates a basic helix-loop-helix (bHLH) transcriptional cascade that regulates the level of delta expression. Notch-Intra forms a transcriptional complex with a bHLH protein, suppressor of hairless, which binds to and activates the gene encoding a second bHLH protein, enhancer of split. Once activated, enhancer of split binds to and represses expression of the gene encoding a third bHLH protein, achaetescute. Achaete-scute activity promotes expression of delta. Thus, by repressing achaete-scute, enhancer of split decreases transcriptional activation of the Delta gene and production of Delta protein. This diminishes the ability of the cell on the right to activate Notch signaling in the left cell.

C. Once the level of Notch signaling in the left cell has been reduced, suppressor of hairless no longer activates enhancer of split, and the level of expression of achaete-scute increases, resulting in enhanced expression of Delta and further activation of Notch signaling in the right cell. In this way a small initial imbalance in Delta-Notch signaling is rapidly amplified into a marked asymmetry in the level of Notch activation in the two cells. In the mammalian central nervous system cells with high levels of Notch activation are diverted from neuronal fates, whereas cells with low levels of Notch activation become neurons.

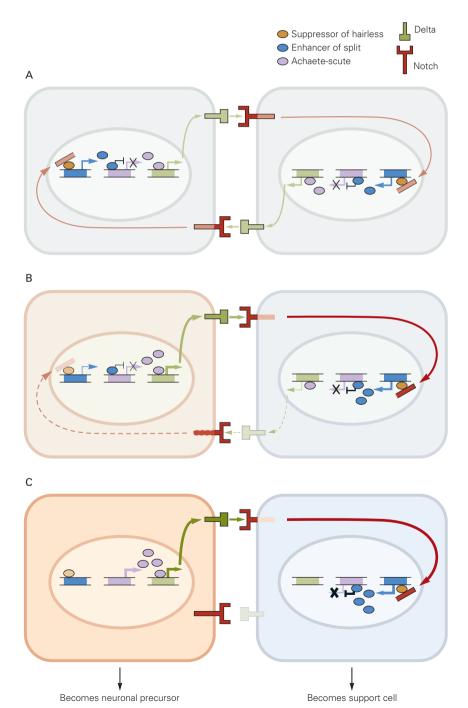

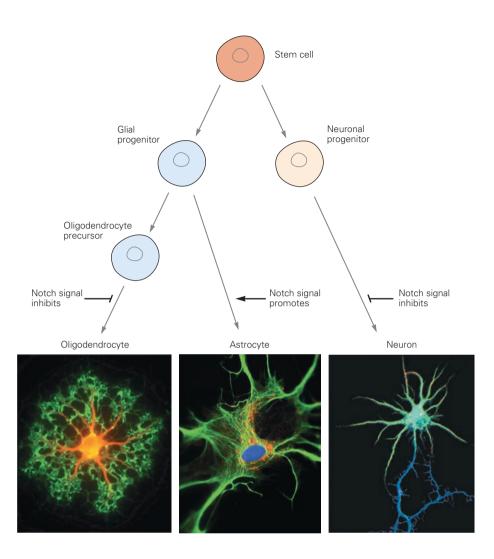

Figure 53-4 Notch signaling regulates the fate of cells in the developing cerebral cortex. Notch signaling has several roles in cell differentiation in the developing cerebral cortex. The activation of Notch signaling in glial progenitor cells results in the differentiation as astrocytes and inhibits differentiation as oligodendrocytes (left pathway). Notch signaling also inhibits progenitor cells from differentiating into neurons (right pathway). (Photo on left reproduced, with permission, from David H. Rowitch; middle photo reproduced, with permission, from Edward Nyatia and Dirk Michael Lang/SA Science Lens Competition(SAASTA); photo on right reproduced, with permission, from Masatoshi Takeichi, Riken Center for Developmental Biology.

is preferentially localized in neuronal daughters and antagonizes notch signaling. As a consequence, loss of numb activity causes progenitor cells to proliferate extensively. The inhibition of notch signaling results in the expression of several proneural bHLH transcription factors, notably Mash1, neurogenin-1, and neurogenin-2. Neurogenins promote neuronal production by activating downstream bHLH proteins such as neuroD, and they block the formation of astrocytes by inhibiting JAK and STAT signaling.

Although delta-notch signaling and bHLH transcription factor activators lie at the heart of the decision to produce neurons or glial cells, several additional transcriptional pathways augment this core molecular program. One important transcription factor, REST/NRSF, is expressed in neural progenitors and glial cells, where it represses the expression of neuronal genes.

REST/NRSF rapidly degrades as neurons differentiate, permitting the expression of neurogenic bHLH factors and other neuronal genes. Homeodomain transcription factors of the SoxB class also play an important role in maintaining neural progenitors by blocking neurogenic bHLH protein activity. The differentiation of neurons therefore requires the avoidance of REST/NRSF and SoxB protein activity.

Neuronal Migration Establishes the Layered Organization of the Cerebral Cortex

The mammalian cerebral cortex develops in three main stages: a preplate, a cortical plate, and finally the mature pattern of layers. Neural precursors in the ventricular zone of the preplate differentiate into neurons that migrate along radial glial fibers before settling in the cortical plate. These migratory cells divide the preplate into a subplate and a marginal zone (Figure 53–5).

Once within the cortical plate, neurons become organized into well-defined layers. The laminar settling position of a neuron is correlated precisely with its *birthday*, a term that refers to the time at which a dividing precursor cell undergoes its final round of cell division and gives rise to a postmitotic neuron. Cells that migrate from the ventricular zone and leave the cell cycle at early stages give rise to neurons that settle in the deepest layers of the cortex. Cells that exit the cell cycle at progressively later stages migrate over longer distances and pass earlier-born neurons, before settling in more superficial layers of the cortex. Thus the layering of neurons in the cerebral cortex follows an inside-first, outside-last rule (Figure 53–6A).

Disruption in the migratory and settling programs of cortical neurons underlies much human cortical pathology (Figure 53–6C, D). In *lissencephaly* (Greek,

smooth brain, referring to the characteristic smoothing of the cortical surface in patients with the disorder) neurons leave the ventricular zone but fail to complete their migration into the cortical plate. As a result, the mature cortex is typically reduced from six to four neuronal layers, and the arrangement of neurons in each remaining layer is disordered. Occasionally, lissencephaly is accompanied by the presence of an additional group of neurons in the subcortical white matter. Patients with lissencephalies from mutations in the Lis1 and doublecortin genes often suffer severe mental retardation and intractable epilepsy. The Lis1 and doublecortin proteins have been localized to microtubules, suggesting they are involved in microtubule-dependent nuclear movement, although their precise functions in neuronal migration remain unclear.

Mutations that disrupt the reelin signaling pathway disrupt the final stage of neuronal migration through the cortical subplate. Reelin is an extracellular matrix protein that is secreted from the Cajal-Retzius cells, a class of neurons found in the preplate and marginal

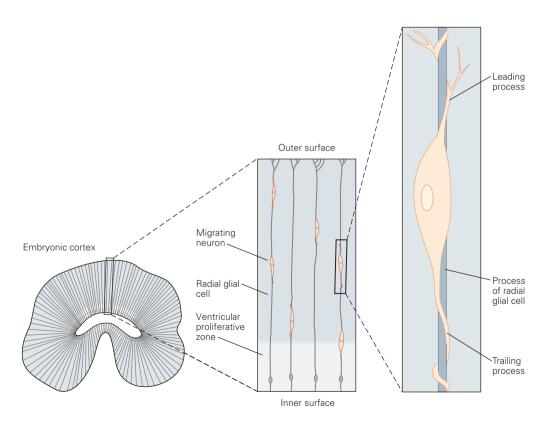

Figure 53–5 Neurons migrate along radial glial cells. After their generation from radial glial cells, newly generated neurons in the embryonic cerebral cortex extend a leading process that

wraps around the shaft of the radial glial cell, thus using the radial glial cells as scaffolds during their migration from the ventricular zone to the pial surface of cortex.

zone. Signals from these cells are crucial for the migration of cortical neurons. In mice lacking functional reelin, neurons fail to detach from their radial glial scaffolds and pile up underneath the cortical plate, disobeying the inside-out migratory rule. As a consequence, the normal layering of cell types is inverted and the marginal zone is lost. Reelin acts through cell-surface receptors that include the ApoE receptor 2 and the very low-density lipoprotein receptor. The binding of reelin to these receptors activates an intracellular protein, Dab1, which transduces reelin signals. Cadherin-like adhesion proteins may also be involved in transducing reelin signals. Not surprisingly, the loss of proteins that transduce reelin signals produce similar migratory phenotypes.

Central Neurons Migrate Along Glial Cells and Axons to Reach Their Final Settling Position

The migration of neurons follows one of three major programs, termed *radial*, *tangential*, and *free* migration. With radial migration central neurons move along the long unbranched processes of radial glial cells. With tangential migration central neurons use axonal tracts as their guides. Free migration occurs in the peripheral nervous system without radial glia or axonal tracts.

Glial Cells Serve As a Scaffold in Radial Migration

Classical anatomical studies of cortical development in the primate brain in the 1970s provided evidence that neurons generated in the ventricular zone migrate to their settling position along a pathway of radial glial fibers. Radial glial cells serve as the primary scaffold for radial neuronal migration. Their cell bodies are located close to the ventricular surface and give rise to elongated fibers that span the width of the developing cerebral wall. Each radial glial cell has one basal endfoot in the ventricular zone at the apical surface and processes that terminate in multiple end-feet at the pial surface of the brain (Figure 53–5). Radial glial scaffolds are especially important in the development of the primate cortex, where neurons are required to migrate over long distances as the cerebral wall expands.

Most radial glial cells are transient structures; as we have seen, they give rise to neurons and eventually differentiate into astrocytes. A single radial glial cell scaffold can support the migration of up to 30 generations of cortical neurons.

What forces and molecules power neuronal migration on radial glial cells? After a neuron leaves the cell cycle its leading process wraps around the shaft of the radial glial cell and its nucleus translocates within the cytoplasm of the leading process. Although the leading process of the migrating neuron extends slowly and steadily, the nucleus moves in an intermittent, stepwise manner because of complex rearrangements of the cytoskeleton. A microtubular lattice forms a cage around the nucleus, and movement of the nucleus depends on a centrosome-like structure, termed a basal body, which projects a system of microtubules into the leading process, providing the conduit for nuclear movement (Figure 53-7A). Defects in neuronal migration that result from loss of Lis1 or doublecortin (Figure 53-6) reflect the critical role of these genes in microtubular assembly and function.

Neuronal migration along radial glia also involves adhesive interactions between cells. Adhesive receptors such as integrins promote neuronal extension on radial glial cells. The migration of neurons along glial fibers is nevertheless different from the extension of axons driven by growth cones (see Chapter 54). In neuronal migration the leading process is devoid of the structured actin filaments that typify growth cones and more closely resembles an extending dendrite, an inference made first by Santiago Ramon y Cajal.

Axon Tracts Serve As a Scaffold for Tangential Migration

The second prominent mechanism of neuronal translocation in the developing brain is tangential migration. This form of migration is used to populate distinct regions of the nervous system and may have evolved as a mechanism for increasing the complexity of neuronal circuits. Its major cellular substrate appears to be preexisting axonal tracts that connect regions of neuronal generation with the final settling position of the neurons. In the developing cortex the axons of cortical projection neurons reach the internal capsule just as migratory neurons begin to enter the neocortex; at this intersection immigrating neurons are tightly associated with the bundles of axons that leave the cortex.

Neurons that use tangential migration follow precise routes of navigation and settling. This can best be seen in the ventral telencephalon, which contains two major sites of neuronal production, the medial and lateral ganglionic eminences. Some of the neurons generated in this region are destined to populate the basal

ΜZ VΖ B Wild type (late) C Reelin mutant D Doublecortin mutant 2 6 5 3 4 3 5 SP WM WM VΖ WM

A Cortical cells follow "inside-first outside-last" pattern of migration

Figure 53–6 The migration of neurons in the cerebral cortex is responsible for the layered organization of the cortex. (Modified, with permission, from Olsen and Walsh 2002.)

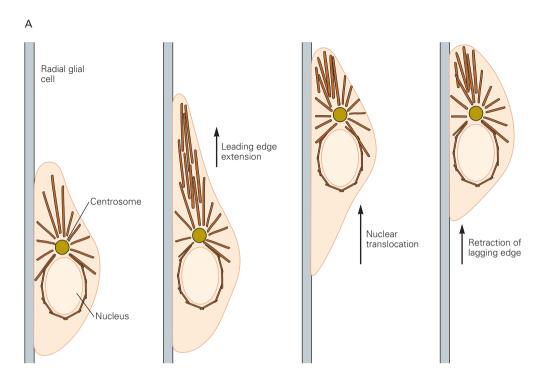

A. During normal cortical development neurons use radial glial cells as migratory scaffolds as they enter the cortical plate. As they approach the pial surface, neurons stop migrating and detach from radial glial cells. (CP, cortical plate; MZ, marginal zone; VZ, ventricular zone.)

B. An orderly inside-out pattern of neuronal migration results in the formation of six neuronal layers in the mature cerebral

cortex, arranged between the white matter (WM) and subplate (SP).

C. In the mouse mutant *reeler*, which lacks functional reelin protein, the layering of neurons in the cortical plate is severely disrupted and partially inverted. In addition, the entire cortical plate develops beneath the subplate.

D. In *doublecortin* (*dcx*) mutants the cortex is thickened, neurons lose their characteristic layered identity, and some layers contain fewer neurons. A similar disruption is observed in *Lis1* mutants, which underlies certain forms of human lissencephaly.

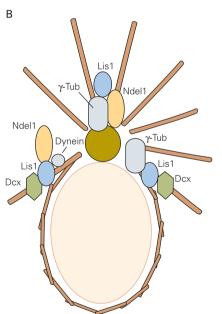

Figure 53–7 Neurons migrate along radial glial cells with the help of microtubule-associated motors.

A. The microtubular cytoskeleton has an important role in neuronal migration. Microtubules envelop the nucleus in a cage-like structure. Migration involves elongation of the leading process of the neuron in the direction of movement, under the control of attractive and repellant extracellular guidance cues. These cues regulate the phosphorylation status of the microtubule-associated proteins Ndel1 and Lis1 (two components of the dynein motor complex) and of doublecortin (Dcx), which together stabilize the microtubule cytoskeleton. The centrosome then moves into the elongated process, the nucleus is pulled in the direction of the centrosome by the dynein complex, and the two become attached. Disruption of Dcx, Ndel1, or Lis1 impairs interaction between the nucleus and centrosome and disrupts neuronal migration. (Modified, with permission, from Gleeson and Walsh 2000.)

B. Microtubules are attached to the centrosome by a series of proteins that are targets for disruption in neuronal migration disorders.

ganglia. Tangential migration of neurons from these ventral structures also provides the cerebral cortex, hippocampus, and olfactory bulb with interneurons.

Neurons generated in the medial ganglionic eminence migrate tangentially and settle in the neocortex where they give rise to many interneuron populations, including Cajal-Retzius neurons. Thus cortical neurons

originate from two sources: Excitatory neurons from the cortical ventricular zone and interneurons from the medial ganglionic eminence. In contrast, neurons generated in the lateral ganglionic eminence migrate rostrally and contribute the periglomerular and granule interneurons of the olfactory bulb (Figure 53–8). In this rostral migratory stream neurons use neighboring neurons as substrates for migration (chain migration). In the adult brain neurons that follow the rostral migratory stream originate instead in the subventricular zone of the striatum.

Transcription factors control the character of ganglion eminence neurons and ensure their tangential migration. The homeodomain proteins Dlx1 and Dlx2 are expressed by cells in the ganglionic eminences. In mice lacking Dlx1 and Dlx2 activity the perturbation of neuronal migration leads to a profound reduction in the number of GABAergic interneurons in the cortex. Similarly, in mice lacking the gene encoding the homeodomain transcription factor Gsh2 the rostral migratory stream is disrupted and the arrival of interneurons in the olfactory bulb is delayed.

Neural Crest Cell Migration in the Peripheral Nervous System Does Not Rely on Scaffolding

The peripheral nervous system derives from neural crest stem cells, a small group of neuroepithelial cells at the boundary of the neural tube and epidermal ectoderm. Soon after their induction neural crest cells are transformed from epithelial to mesenchymal cells and begin to delaminate from the neural tube. They then migrate to many sites throughout the body. Neural crest cell migration does not rely on scaffolding (ie, radial glial cells or preexisting axon tracts) and thus is called free migration. This form of neuronal migration

requires significant cytoarchitectural and cell adhesive changes and differs from most of the migratory events in the central nervous system.

Bone morphogenetic protein (BMP) signaling is critical for neural crest induction (see Chapter 52), as well as neural crest migration. Exposure of neural epithelial cells to BMPs triggers molecular changes that convert epithelial cells to a mesenchymal state, causing them to delaminate from the neural tube and migrate into the periphery. BMPs trigger changes in neural crest cells by inducing expression of transcription factors, notably the zinc finger proteins snail, slug, and twist, which have a conserved role in promoting epithelialto-mesenchymal transitions. These transcription factors direct expression of proteins that regulate the properties of the cytoskeleton as well as enzymes that degrade extracellular matrix proteins. These enzymes give neural crest cells the ability to break down the basement membrane surrounding the epithelium of the neural tube, permitting them to embark on their migratory journey into the periphery.

As neural crest cells begin to delaminate, their expression of cell adhesion molecules changes. Alterations in expression of adhesive proteins, notably cadherins, permit neural crest cells to loosen their adhesive contacts with neural tube cells and begin the delamination process. Neural crest cells also begin to express integrins, receptors for extracellular matrix proteins such as laminins and collagens that are found along peripheral migratory paths.

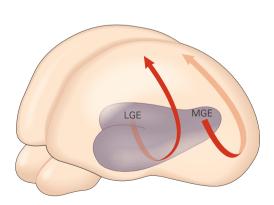

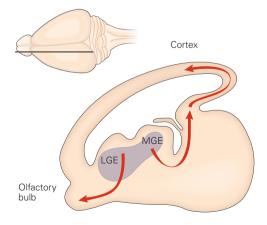

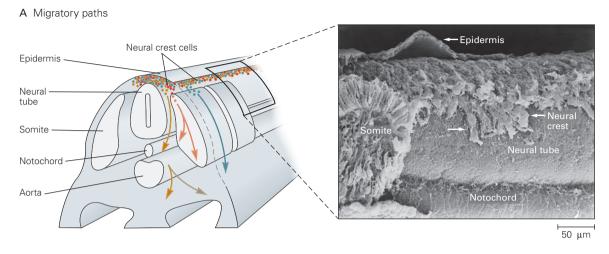

Figure 53–8 Interneurons generated in the ventral telencephalon migrate tangentially to the cerebral cortex. Neurons generated in the medial ganglionic eminences (MGE) migrate tangentially and settle in the neocortex. On arrival they give rise to interneurons, including Cajal-Retzius neurons. Neurons generated in the lateral ganglionic eminence (LGE)

migrate rostrally and contribute the periglomerular and granule interneurons of the olfactory bulb. Neurons migrating to the olfactory bulb use neighboring migrating cells as substrates for migration (a process called chain migration). (Adapted from Rallu, Corbin and Fishell 2002.)

B Final positions

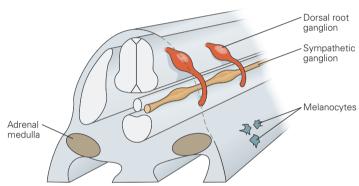

Figure 53–9 Neural crest cell migration in the peripheral nervous system.

A. A cross section through the middle part of the trunk of a chick embryo shows the main pathways of neural crest cells. Some migratory cells migrate along a superficial pathway, just beneath the ectoderm, and differentiate into pigment cells of the skin. Others migrate along a deeper pathway that takes them through the somites, where they coalesce to form dorsal

root sensory ganglia. Still others migrate between the neural tube and somites, past the dorsal aorta. These cells differentiate into sympathetic ganglia and adrenal medulla. The scanning electron micrograph shows neural crest cells migrating away from the dorsal surface of the neural tube of a chick embryo. (Micrograph, used with permission, courtesy of K. Tosney.)

B. The final settling positions of neural crest cells, after they have completed their migration and undergone differentiation.

The first structures encountered by migrating neural crest cells are somites, epithelial cells that later give rise to muscle and cartilage. Neural crest cells pass through the anterior half of each somite but avoid the posterior half (Figure 53–9). The rostral channeling of migratory neural crest cells is imposed by ephrin B proteins, which are concentrated in the posterior half of each somite. Ephrins provide a repellant signal that interacts with EphB class tyrosine kinase receptors on neural crest cells to prevent their invasion. Neural crest cells that remain within the anterior sclerotome of the somite differentiate into sensory neurons of the dorsal root ganglia; those that migrate around the dorsal region of the somite approach the skin and give rise to melanocytes.

Differentiation of neural crest cells into dorsal root ganglion neurons is initiated at the time the cells emigrate from the neural tube, and depends on early exposure to Wnt signals secreted from the dorsal neural tube and somites as well as expression of neurogenin bHLH factors. In contrast, those neural crest cells that follow a more medial and ventral migratory path are exposed to BMPs secreted from the dorsal aorta and develop as sympathetic neurons that acquire a non-adrenergic phenotype. BMPs promote noradrenergic neuronal differentiation by inducing the expression of a variety of transcription factors that include the bHLH protein Mash1, the homeodomain protein Phox2, and the zinc finger protein Gata2 (Figure 53–10).

The Neurotransmitter Phenotype of a Neuron Is Plastic

Neurons continue to develop after they have migrated to their final position, and no aspect of their later differentiation is more important than the choice of chemical neurotransmitter. The migratory pathway that a neural crest cell pursues to reach its final location exposes the cell to environmental signals that have a critical role in determining its transmitter phenotype.

The Transmitter Phenotype of a Peripheral Neuron Is Influenced by Signals from the Neuronal Target

The transmitter phenotype of autonomic neurons is plastic, and the final transmitter phenotype is determined in part by the end organs they innervate. Most sympathetic neurons use norepinephrine as their primary transmitter. However, those that innervate the exocrine sweat glands in the foot pads use acetylcholine, and even these neurons express norepinephrine at the time they first innervate the sweat glands of the skin. Only after their axons have contacted the sweat glands do they stop synthesizing norepinephrine and start producing acetylcholine.

When the sweat glands from the foot pad of a newborn rat are transplanted into a region that is normally innervated by noradrenergic sympathetic neurons, the synaptic neurons acquire cholinergic transmitter properties, indicating that cells of the sweat gland secrete factors that induce cholinergic properties in sympathetic neurons.

Several secreted factors trigger the switch from a noradrenergic to cholinergic phenotype in sympathetic neurons. The sweat gland secretes a cocktail of interleukin 6-like cytokines, notably cardiotrophin-1, leukemia inhibitory factor, and ciliary neurotrophic factor. Several aspects of neuronal metabolism that are linked to transmitter synthesis and release are controlled by these factors. The neurons stop producing the large dense-core granules characteristic of noradrenergic neurons and start making the small electron-translucent vesicles typical of cholinergic neurons (Figure 53–11).

The Transmitter Phenotype of a Central Neuron Is Controlled by Transcription Factors

Neurons that populate the central nervous system use two major neurotransmitters. The amino acid L-glutamate is the major excitatory transmitter and GABA is the major inhibitory transmitter. Distinct molecular programs are used to establish neurotransmitter phenotype in different brain regions and neuronal classes. We shall illustrate the general strategy for assignment of amino acid neurotransmitter phenotypes by focusing on neurons in the cerebral cortex and cerebellum.

The cerebral cortex contains glutamatergic pyramidal neurons that are generated within the cortical plate and rely on the bHLH factors neurogenin-1 and neurogenin-2 for their differentiation. In contrast, as

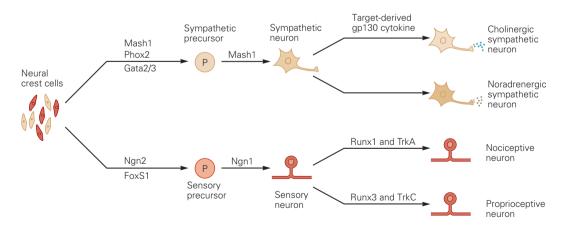

Figure 53–10 Neural crest cells differentiate into sympathetic and sensory neurons. The neuronal fates of trunk neural crest cells are controlled by transcription factor expression. Expression of the bHLH protein Mash1 directs neural crest cells along a sympathetic neuronal pathway. Sympathetic neurons can acquire noradrenergic or cholinergic transmitter phenotypes depending on the target cells they innervate and

the level of gp130 cytokine signaling (see Figure 53–11). Two bHLH proteins, neurogenin-1 and -2, direct neural crest cells along a sensory neuronal pathway. Sensory neurons that express the transcription factor Runx1 and the tyrosine kinase receptor TrkA become nociceptors, whereas those that express Runx3 and TrkC become proprioceptors.

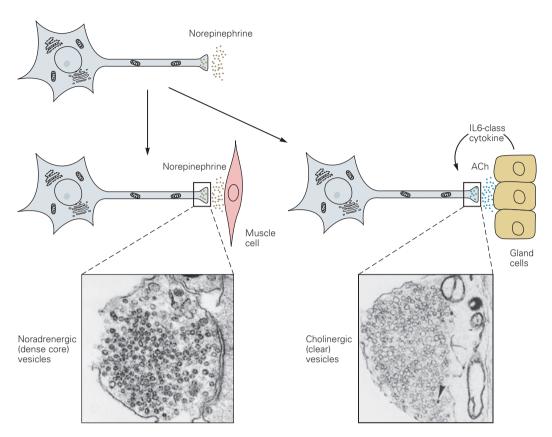

Figure 53–11 The target of sympathetic neurons determines neurotransmitter phenotype. Sympathetic neurons are initially specified with a noradrenergic transmitter phenotype. Most sympathetic neurons, including those that innervate cardiac muscle cells, retain this transmitter phenotype, and their terminals are packed with the dense-core vesicles in which norepine-phrine is stored. But the sympathetic neurons that innervate sweat gland targets are induced to switch to a cholinergic

transmitter phenotype; their terminals become filled with the small clear vesicles in which acetylcholine (ACh) is stored. Sweat gland cells direct the switch in transmitter phenotype by secreting members of the interleukin cytokine family. Several members of this family, including leukemia inhibitory factor (LIF) and ciliary neurotrophic factor (CNTF), are potent inducers of cholinergic phenotype in sympathetic neurons grown in cell culture. (Micrographs reproduced, with permission, courtesy of S. Landis.)

we discussed earlier in the chapter (see "Axons Tracts Serve As a Scaffold for Tangential Migration"), most GABAergic inhibitory interneurons migrate into the cortex from the ganglionic eminences, and their inhibitory transmitter character is specified by the bHLH protein Mash1 (Figures 53–12A) as well as by the Dlx1 and Dlx2 proteins.

Similarly, the cerebellum contains several different classes of inhibitory neurons (Purkinje, Golgi, basket, and stellate neurons) and two major classes of excitatory neurons (granule neurons and large cerebellar nuclear neurons). These inhibitory and excitatory neurons have different origins; GABAergic neurons derive from the ventricular zone, whereas glutamatergic neurons migrate into the cerebellum from the rhombic lip. The generation of GABAergic and glutamatergic neurons is controlled by two different bHLH transcription

factors, Ptf1a for inhibitory and Math-1 for excitatory neurons (Figure 53–12B). These bHLH factors are expressed by neuroepithelial cells but not by mature neurons, implying that differentiation into glutamatergic and GABAergic neurons is initiated prior to neuronal generation.

The Survival of a Neuron Is Regulated by Neurotrophic Signals from the Neuron's Target

Not all neurons are destined to survive, and decisions about life and death are therefore aspects of a neuron's fate. The surprising and counterintuitive fact is that cell death is preprogrammed in most animal cells, including neurons.

The Neurotrophic Factor Hypothesis Was Confirmed by the Discovery of Nerve Growth Factor

The target of a neuron is a key source of factors essential for the neuron's survival. The critical role of target cells in neuronal survival was discovered in studies of the dorsal root ganglia.

In the 1930s Samuel Detwiler and Viktor Hamburger discovered that the number of sensory neurons in embryos is increased by transplantation of an additional limb bud into the target field and decreased if the limb target is removed. At the time these findings were thought to reflect an influence of the limb

on the proliferation and subsequent differentiation of sensory neuron precursors. In the 1940s, however, Rita Levi-Montalcini made the startling observation that the death of neurons is not simply a consequence of pathology or experimental manipulation, but rather occurs during the normal program of embryonic development. Levi-Montalcini and Hamburger went on to show that removal of a limb leads to the excessive death of sensory neurons rather than a decrease in their production.

These early discoveries on the life and death of sensory neurons were quickly extended to neurons in the central nervous system. Hamburger found that

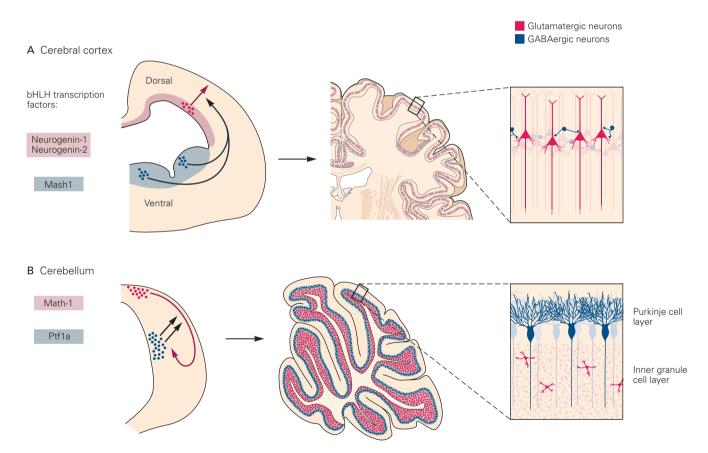

Figure 53–12 The neurotransmitter phenotype of central neurons is controlled by basic helix-loop-helix transcription factors.

A. In the cerebral cortex GABAergic and glutamatergic neurons derive from different proliferative zones and are specified by different basic helix-loop-helix (bHLH) transcription factors. Glutamatergic pyramidal neurons derive from the cortical ventricular zone, and their differentiation depends on the activities of neurogenin-1 and -2. The differentiation of GABAergic interneurons in the ganglionic eminences of the ventral telencephalon depends on the bHLH protein Mash1. These neurons migrate

dorsally to supply the cerebral cortex with most of its inhibitory interneurons (see Figure 53–8).

B. In the developing cerebellum GABAergic and glutamatergic neurons also derive from different proliferative zones and are specified by bHLH transcription factors. Glutamatergic granule cells migrate into the cerebellum from the rhombic lip, settle in the inner granular layer (IGL), and are specified by the bHLH protein Math-1. GABAergic Purkinje neurons migrate from the deep cerebellar proliferative zone, settle in the Purkinje cell layer (PCL), and are specified by the bHLH protein Ptf1a.

approximately half of all motor neurons generated in the spinal cord die during embryonic development. Moreover, in experiments similar to those performed on sensory ganglia, Hamburger discovered that motor neuron death could be increased by removing a limb and reduced by adding an additional limb (Figure 53–13). These findings indicate that signals from target cells are critical for the survival of neurons within the central as well as peripheral nervous system. We now know that the phenomenon of neuronal overproduction, followed by a phase of neuronal death, occurs in most regions of the vertebrate nervous system. Blocking neuromuscular activity with drugs such as curare also reduces the extent of motor neuron death (Figure 53–13).

The early discoveries of Levi-Montalcini and Hamburger laid the foundations for the *neurotrophic factor hypothesis*. The core of this hypothesis is that cells at or near the target of a neuron secrete small amounts of an

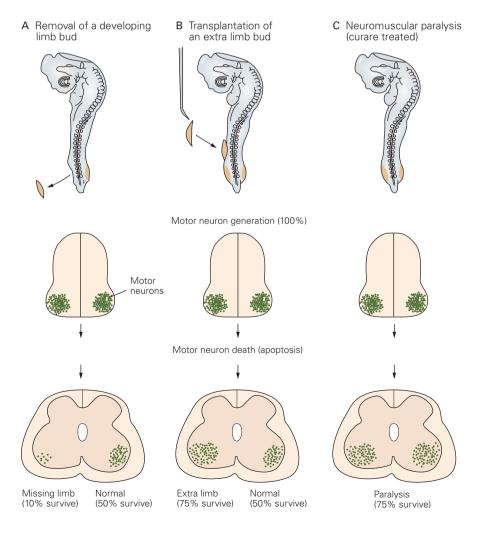

essential nutrient or trophic factor, and that the uptake of this factor by nerve terminals is needed for the survival of the neuron (Figure 53–14). This hypothesis was dramatically confirmed in the 1970s when Levi-Montalcini and Stanley Cohen purified the protein we now know as nerve growth factor (NGF) in the early 1970s and showed that this protein is made by target cells and supports the survival of sensory and sympathetic neurons in vitro. Moreover, neutralizing antibodies directed against NGF were found to cause a profound loss of sympathetic and sensory neurons in vivo.

Neurotrophins Are the Best Studied Neurotrophic Factors

The discovery of NGF prompted a search for additional neurotrophic factors. Today we know of over a dozen secreted factors that promote neuronal survival.

Figure 53–13 The survival of motor neurons depends on signals provided by their muscle targets. The role of the muscle target in motor neuron survival was demonstrated by Viktor Hamburger in a classic series of experiments performed in the chick embryo. (Adapted, with permission, from Purves and Lichtman 1985.)

- A. A limb bud was removed from a 2.5-day-old chick embryo soon after the arrival of motor nerves. A section of the lumbar spinal cord 1 week later reveals few surviving motor neurons on the deprived side of the spinal cord. The number of motor neurons on the contralateral side with an intact limb is normal
- B. An extra limb bud was grafted adjacent to a host limb prior to the normal period of motor neuron death. A section of the lumbar spinal cord 2 weeks later shows an increased number of limb motor neurons on the side with the extra limb.
- C. Blockade of nerve-muscle activity with the toxin curare, which blocks acetylcholine receptors, rescues many motor neurons that would otherwise die. Curare may act by enhancing the release of trophic factors from inactive muscle.

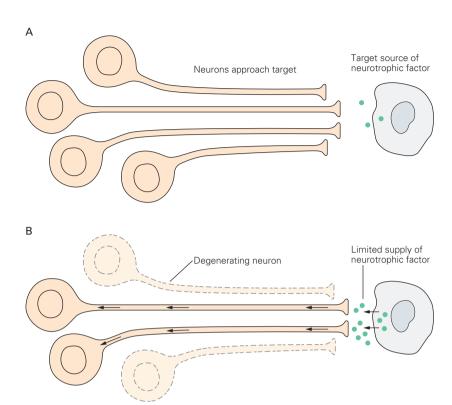

Figure 53–14 The neurotrophic factor hypothesis. (Adapted, with permission, from Reichardt and Farinas 1997.)

A. Neurons extend their axons to target cells, which secrete low levels of neurotrophic factors. (For simplicity only one target cell is shown.) The neurotrophic factor binds to specific receptors and is internalized and transported to the cell body, where it promotes neuronal survival.

B. Neurons that fail to receive adequate amounts of neurotrophic factor die through a program of cell death termed apoptosis.

The best studied of the neurotrophic factors are related to NGF and are called the neurotrophin family.

There are three main neurotrophins: NGF itself, brain derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3). Other classes of proteins that promote neuronal survival include members of the transforming growth factor β family, the interleukin 6-related cytokines, fibroblast growth factors, and even certain inductive signals we encountered earlier (BMPs and hedgehogs). Other neurotrophic factors, notably members of the glial cell line-derived neurotrophic factor (GDNF) family, are responsible for the survival of different types of sensory and sympathetic neurons (Figure 53–15).

Neurotrophins interact with two major classes of receptors, the Trk receptors and p75. Neurotrophins promote cell survival and promote cell death through activation of Trk receptors, whereas signaling through the p75 receptor promotes cell death. The Trk family comprises three membrane-spanning tyrosine kinases named TrkA, TrkB, and TrkC, each of which exists as a dimer (Figure 53–16).

As with other tyrosine kinase receptors, the binding of neurotrophins to Trk receptors leads to phosphorylation of an intracellular domain of the receptor, resulting in the dimerization of Trk proteins and phosphorylation of specific tyrosine residues in the activation loop of the kinase domain. Phosphorylation of these residues leads to a conformational change in the receptor and to phosphorylation of tyrosine residues that serve as docking sites for adaptor proteins. Activation of Trk receptors promotes the survival of neurons and also triggers their differentiation. These divergent biological responses involve different intracellular signaling pathways: neuronal differentiation largely by the mitogen-activated kinase (MAPK) enzymatic pathways and survival largely by the phosphatidylinositol-3 kinase pathway (Figure 53–17).

In contrast to the specificity of Trk receptor interactions, all neurotrophins bind the receptor p75 (Figure 53–16). The activation of p75 promotes neuronal survival through a pathway that involves activation of the NF-B enzyme. In the absence of exposure to neurotrophins, p75 receptor activation promotes neuronal death. Receptor p75 is a member of the tumor necrosis factor (TNF) receptor family and promotes cell death by activating proteases of the caspase family, which we discuss below.

Neurotrophin signaling is relayed from the axon terminal to the cell body of the neuron through a process that involves internalization of a complex of neurotrophin bound to Trk receptors. The retrograde

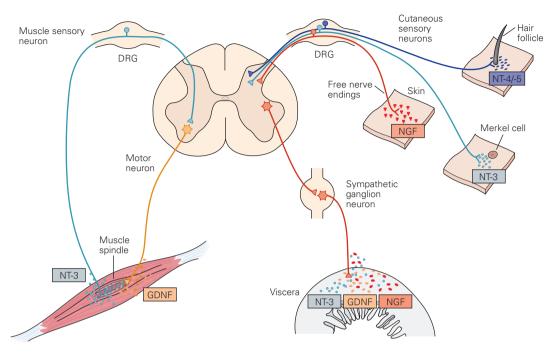

Figure 53–15 Different neurotrophic factors promote the survival of distinct populations of dorsal root ganglion neurons. Proprioceptive sensory neurons that innervate muscle spindles depend on neurotrophin-3 (NT-3); nociceptive neurons that innervate skin depend on nerve growth factor (NGF); mechanoreceptive neurons that innervate Merkel cells

depend on neurotrophin-3; and those that innervate hair follicles depend on neurotrophin-4 and -5 (NT-4/-5). Motor neurons depend on glial cell line-derived neurotrophic factor (GDNF) and other factors. Sympathetic neurons depend on NGF, NT-3, and GDNF. (Adapted, with permission, from Reichardt and Farinas 1997.)

transport of this complex occurs in a class of endocytotic vesicles called signaling endosomes. The transport of these vesicles brings activated Trk receptors into cellular compartments able to activate signaling pathways and transcriptional programs essential for neuronal survival.

The picture is more complex for neurons in the central nervous system. The survival of motor neurons, for example, is not dependent on a single neurotrophic factor; different classes of motor neurons require neurotrophins, glial cell line-derived neurotrophic factor (GDNF), and interleukin-6-like proteins expressed by

Figure 53–16 Neurotrophins and their receptors. Each of the three main neurotrophins interacts with a different transmembrane tyrosine kinase receptor (Trk). In addition, all three neurotrophins can bind to the low-affinity neurotrophin receptor p75. (BDNF, brain-derived neurotrophic factor; NGF, nerve growth factor; NT-3, neurotrophin-3.) (Adapted, with permission, from Reichardt and Farinas 1997.)

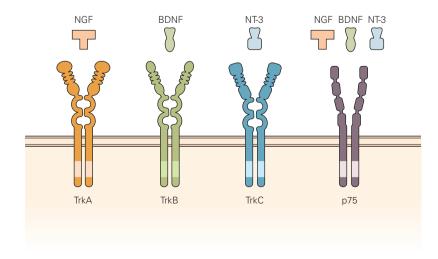

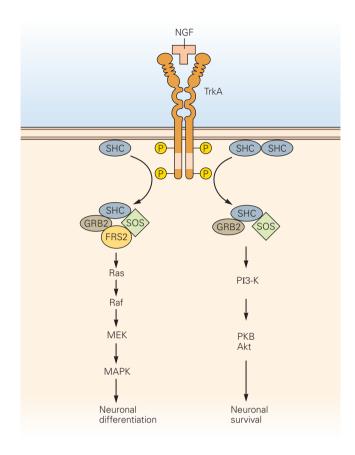

Figure 53–17 Binding of nerve growth factor to the TrkA receptor activates alternative intracellular signaling pathways. The binding of nerve growth factor (NGF) induces dimerization of the TrkA receptor, which triggers its phosphorylation at many different residues. Phosphorylation of TrkA results in the recruitment of the adaptor proteins SHC, GRB2, and SOS. The additional recruitment of FRS2 to this complex (left) activates a Ras kinase signaling pathway that promotes neuronal differentiation. In the absence of FRS2 (right) the complex activates a phosphatidylinositol-3 kinase (PI3-K) pathway that promotes neuronal survival. (Akt/PKB, protein kinase B; MAPK, microtubule-associated protein kinase; MEK, mitogen-activated/ERK kinase.) (Adapted, with permission, from Reichardt and Farinas 1997.)

muscles or peripheral glial cells. The survival of these neuronal classes depends on the exposure of axons to local neurotrophic factors.

Neurotrophic Factors Suppress a Latent Death Program in Cells

Neurotrophic factors were once believed to promote the survival of neural cells by stimulating their metabolism in beneficial ways, hence their name. It is now evident, however, that neurotrophic factors suppress a latent death program present in all cells of the body, including neurons.

This biochemical pathway can be considered a suicide program. Once it is activated, cells die by *apoptosis* (Greek, falling away): They round up, form blebs, condense their chromatin, and fragment their nuclei. Apoptotic cell deaths are distinguishable from *necrosis*, which typically results from acute traumatic injury and involves rapid lysis of cellular membranes without activation of the cell death program.

The first clue that deprivation of neurotrophic factors kills neurons by unleashing an active biochemical

program emerged from studies that assessed neuronal survival after inhibition of RNA and protein synthesis. Exposure of sympathetic neurons to protein synthesis inhibitors was found to prevent the death of sympathetic neurons triggered by removal of NGF. These results sparked the idea that neurons are always capable of synthesizing proteins that are lethal and that NGF prevents their synthesis: Neurotrophins suppress an endogenous death program.

Key insights into the biochemical nature of the endogenous cell death program emerged from genetic studies of the nematode *Caenorhabditis elegans*. During the development of *C. elegans* a precise number of cells is generated and a fixed number of these cells die—the same number from embryo to embryo. The findings prompted a screen for genes that block or enhance cell death, which led to the identification of the cell death (*ced*) genes. Two of these genes, *ced-3* and *ced-4*, are needed for the death of neurons; in their absence every one of the cells destined to die instead survives. A third gene, *ced-9*, is needed for survival, and works by antagonizing the activities of *ced-3* and *ced-4* (Figure 53–18). Thus, in the absence of *ced-9* many additional cells die,

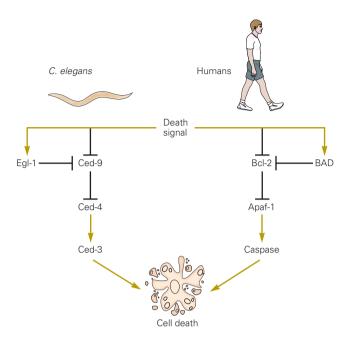

Figure 53-18 Neurons and other cells express a conserved death program. Different cellular insults trigger a genetic cascade that involves a series of death effector genes. These death genes and pathways have been conserved in the evolution of species from worms to humans. The target of the core death pathway is the activation of a set of proteolytic enzymes, the caspases. Caspases cleave many downstream and essential protein substrates (see Figure 53-19), resulting in the death of cells by a process termed apoptosis. Genetic analysis of the worm Caenorhabditis elegans indicates that the Ced-9 protein acts upstream and inhibits the activity of Ced-4 and Ced-3, two proteins that promote cell death. Many vertebrate homologs of Ced-9, the Bcl-2 family of proteins, have been identified. Some of these proteins, such as Bcl-2 itself, inhibit cell death, but others promote cell death by antagonizing the actions of the Bcl-2. The Bcl-2 class proteins act upstream of Apaf-1 (a vertebrate homolog of Ced-4) and the caspases (vertebrate homologs of Ced-3).

even though these deaths still depend on *ced-3* and *ced-4* activity.

The cell death pathway in *C. elegans* has been conserved in mammals. Similar proteins and pathways control the apoptotic death of central and peripheral neurons, indeed of all developing cells. The worm *ced-9* gene encodes a protein that is related to members of the mammalian Bcl-2 family, which protect lymphocytes and other cells from apoptotic death. The worm *ced-3* gene encodes a protein closely related to a class of mammalian cysteine proteases called caspases. The worm *ced-4* gene encodes a protein that is functionally related to a mammalian protein called apoptosis activating factor-1 or Apaf-1.

The mammalian apoptotic cell death pathway works in a way that resembles the worm pathway. The

morphological and histochemical changes that accompany the apoptosis of mammalian cells result from the activation of caspases, which cleave specific aspartic acid residues within cellular proteins. Two classes of caspases regulate apoptotic death: the initiator and effector caspases. Initiator caspases (caspase-8, -9 and -10) cleave and activate effector caspases. Effector caspases (caspase-3 and -7) cleave other protein substrates, so triggering the apoptotic process. Perhaps 1% of all proteins in the cell serve as substrates for effector caspases. Their cleavage contributes to neuronal apoptosis through many pathways: by activation of proteolytic cascades, inactivation of repair, DNA cleavage, mitochondrial permeabilization, and initiation of phagocytosis.

The survival of mammalian neurons is determined by the balance between anti-apoptotic and pro-apoptotic members of the Bcl-2 family of proteins. Some Bcl-2-proteins such as BAX and BAK permeabilize mitochondrial outer membranes, causing the release of pro-apoptotic proteins such as cytochrome c into the cytosol. The release of cytochrome c induces Apaf-1 to bind and activate caspase-9, leading to the cleavage and activation of effector caspases. The binding of neurotrophic factors to their tyrosine kinase receptors is thought to lead to the phosphorylation of protein substrates that promote Bcl-2-like activities (Figure 53–19B). Thus withdrawal of neurotrophic factors from neurons changes the balance from anti-apoptotic to pro-apoptotic members of the Bcl-2 family, which triggers the neuron's demise.

The caspase cell death program can also be activated by many cellular insults, including DNA damage and anoxia (Figure 53–19A). The activation of cell-surface death receptors such as Fas by extracellular ligands results in the activation of caspase-8 or -10 as well as the recruitment of death effector proteins such as FADD. Recruitment of an initiator caspase to the Fas-FADD complex then leads to activation of effector caspases. Because many neurodegenerative disorders result in apoptotic death, pharmacological strategies to inhibit caspases are under investigation.

An Overall View

The nervous system generates an overabundance of neurons and superfluous cells. From beginning to end, intercellular signals provide crucial direction to the developing nervous system. After many years of descriptive embryology we now have the first molecular insights into two fundamental issues in neurogenesis: the mechanisms by which cells acquire neuronal and glial identities and those by which certain young neurons and glial cells survive at the expense of others.

Major insights into these aspects of neurogenesis have emerged from genetic studies of two invertebrate organisms: the fruit fly *Drosophila melanogaster* and the nematode worm *Caenorhabditis elegans*. This research has shown, once again, the striking phylogenetic

conservation of the molecular machinery responsible for animal development. Yet insight into the trophic factors that promote the development and survival of nerve cells came first from studies of vertebrates. Moreover, research on neurotrophic factor signaling and the

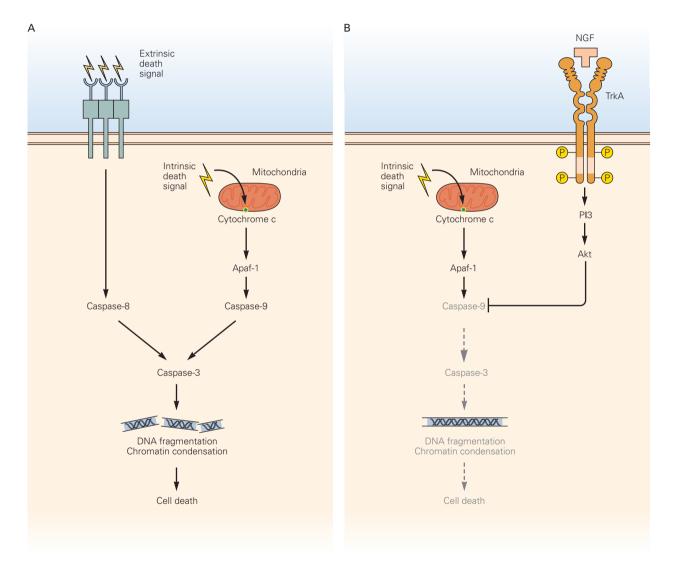

Figure 53–19 Neurotrophic factors suppress caspase activation and cell death. (Adapted, with permission, from Jesenberger and Jentsch 2002.)

A. Two types of pathways trigger cell death: extrinsic activation of surface membrane death receptors and intrinsic activation of a mitochondrial pathway. Both pathways result in activation of caspases such as caspase-8 and caspase-9, which initiate a proteolytic cleavage cascade that converges at the level of caspase-3 activation. Cleavage of the caspase precursor removes the caspase prodomain and produces a proteolytically active enzyme conformation.

The extrinsic pathway involves activation of death receptors by ligands such as tumor-necrosis factor (TNF) receptor 1 or Fas/CD95. The intrinsic pathway involves stress-induced signals such as DNA damage that initiate the release of cytochrome c from the mitochondrial intermembrane space. Cytochrome c binds to Apaf-1 and recruits and activates caspase-9.

B. Binding of neurotrophins to Trk receptors recruits the PI3 kinase pathway and Akt, suppressing the cell death pathway by inhibiting caspase-9. (Akt, protein kinase B [PKB].) This pathway is inhibited in developing neurons by neurotrophic factors explaining why their withdrawal leads to apoptosis.

biochemistry of cell death mechanisms is beginning to be applied to the search for treatment of neurodegenerative disorders.

An Overall View

In the two preceding chapters we saw how neurons are generated in appropriate numbers, at correct times, and in the right places. These early developmental steps set the stage for later events that direct neurons to form functional connections with target cells. To form connections neurons have to extend long processes—axons and dendrites—which permit connectivity with postsynaptic cells and synaptic input from other neurons.

The growing axon may have to travel a long distance—up to several meters in a giraffe—and ignore many inappropriate neuronal partners before terminating in just the right region and recognizing its correct synaptic targets. In this chapter we examine how neurons elaborate axons and dendrites, and how axons are guided to their targets. In subsequent chapters we consider how neurons form synapses and how patterns of connections are shaped by activity.

We begin this chapter by discussing how certain neuronal processes become axons and others dendrites. We then consider the challenges that face an axon as it projects along tortuous pathways to its target. Finally, we illustrate general features of axonal guidance by describing the development of two well-studied axonal pathways: one that conveys visual information from the retina to the brain and another that conveys cutaneous sensory information from the spinal cord to the brain.

Differences in the Molecular Properties of Axons and Dendrites Emerge Early in Development

The processes of neurons vary enormously in their length, thickness, branching pattern, and molecular architecture. Nonetheless, most neuronal processes fit two functional categories: axons and dendrites. More than a century ago Santiago Ramón y Cajal hypothesized that this distinction underlies the ability of neurons to transmit information in a particular direction, an idea he formalized as the law of dynamic polarization.

Cajal wrote that "the transmission of the nerve impulse is always from the dendritic branches and the cell body to the axon." In the decades before electrophysiological methods were up to the task, this law provided a means of analyzing neural circuits histologically. Although exceptions have been found, Ramón y Cajal's law remains a basic principle that relates structure and function in the nervous system and highlights the importance of knowing how neurons acquire their polarized form.

Neuronal Polarity Is Established Through Rearrangements of the Cytoskeleton

Much of our knowledge about neuronal polarization comes from studies of neurons taken from the rodent brain and grown in tissue culture. Hippocampal neurons grown in isolation develop processes reminiscent of those seen in vivo: a single, long, cylindrical axon and several shorter, tapered dendrites (Figure 54–1A). Axons and dendrites soon acquire molecular distinctions, as cytoskeletal and synaptic proteins are targeted to these components. For example, a particular form of the Tau protein is localized in axons and the MAP2 protein in dendrites (Figure 54–1B)

Cultured neurons are especially useful for developmental studies because they initially show no obvious sign of polarization and acquire their specialized features gradually in a stereotyped sequence of cellular steps. This sequence begins with extension of several short processes, each equivalent to the others. Soon thereafter, one process is established as an axon and the remaining processes acquire dendritic features (Figure 54–1A).

How does this occur? Cytoskeletal proteins that maintain elongated processes and drive growth are central to this process. If the actin filaments in an early neurite are destabilized, the ensuing cytoskeletal rearrangements commit the neurite to becoming the axon, while the remaining neurites become dendrites. If the nascent axon is removed, one of the remaining neurites quickly assumes an axonal character. This sequence suggests that axonal specification is a key event in neuronal polarization and that signals from newly formed axons both suppress the generation of additional axons and promote dendrite formation.

The nature of the axonally derived signal that represses other axons is not known. But some insight into signals that control cytoskeletal arrangements has come from the study of a group of proteins encoded by the *Par* complex genes. As first shown in the nematode worm *Caenorhabditis elegans*, Par proteins are involved in diverse aspects of cytoskeletal reorganization, including the polarization of neuronal processes.

Mammalian forebrain neurons lacking *Par3*, *Par4*, *Par6*, or relatives of *Par1* grow multiple processes that are intermediate in length between axons and dendrites and bear markers of both processes (Figure 54–1B).

Although neurons grown in culture are similar to those in the brain, they are deprived of key extrinsic cues and signals. Cultured neurons become randomly arranged with respect to each other, whereas in many regions of the developing brain neurons line up in rows, with their dendrites pointing in the same direction (Figure 54–2A). This difference in vivo and in vitro implies that extrinsic signals regulate the polarization machinery. In the developing brain the local release of semaphorins, and other axonal guidance factors that we discuss later in the chapter, may help to orient dendrites (Figure 54-2C). The job of the Par protein complex is to link these extracellular signals to the cellular machinery that rearranges the cytoskeleton, a process achieved in part through the regulation of proteins that modify actin or tubulin function. In fact both the Tau protein in axons and the MAP2 protein in dendrites associate with and affect microtubules.

If local signals are needed to polarize neurons in the brain, how is polarity established in the uniform environment of a tissue culture? One possible explanation is that minor variations in the intensity of signaling within a neuron, or in signals from its immediate environment, will activate Par proteins in one small domain of the neuron, triggering the nearest process to become an axon. If, by happenstance, one process grows slightly faster than its neighbors, its chances of becoming an axon increase markedly (Figure 54–2B). Presumably, this proto-axonal process emits signals that decrease the chance of other processes following suit, forcing them to become dendrites.

Dendrites Are Patterned by Intrinsic and Extrinsic Factors

Although processes destined to become axons and dendrites initially are indistinguishable, they soon acquire distinct features. Nascent dendrites grow at acute angles and their branches are generally more numerous and closer to the cell body than those of axons. In addition, small protrusions called spines extend from the distal branches of dendrites. Finally, some dendritic branches are retracted or "pruned" to give the arbor its final and definitive shape (Figure 54–3).

Although the core features of dendrite formation are common to many neurons, there is a striking variation in dendrite number, shape, and branching pattern among neuronal types. Indeed, the shape and form of its dendritic arbor is one of the main ways in which

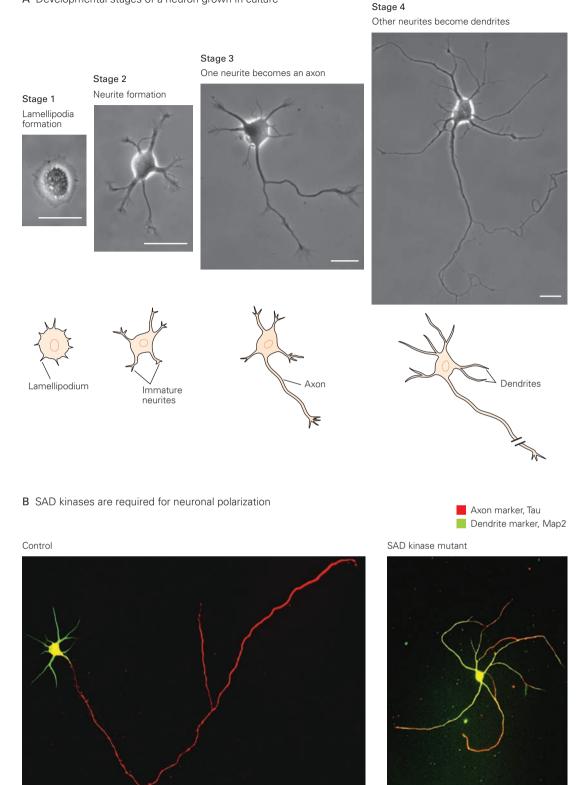

Figure 54–1 The differentiation of axons and dendrites marks the emergence of neuronal polarity.

A. Four stages in the polarization of a hippocampal neuron grown in tissue culture. (Adapted, with permission, from Kaech and Banker 2006.)

B. Hippocampal neurons grown in culture possess multiple short, thick dendrites that are enriched in the microtubule-associated protein MAP2. They also possess a single long axon

that is marked by a dephosphorylated form of the microtubule-associated protein tau (left). A cultured neuron isolated from a mutant mouse lacks expression of a *Par* family gene (SAD kinase). The neuron generates neurites that co-express Tau and MAP2, markers of axons and dendrites respectively. The length and diameter of these neurites are intermediate in size between those of axons and dendrites (right). (Reproduced, with permission, from Kishi et al. 2005.)

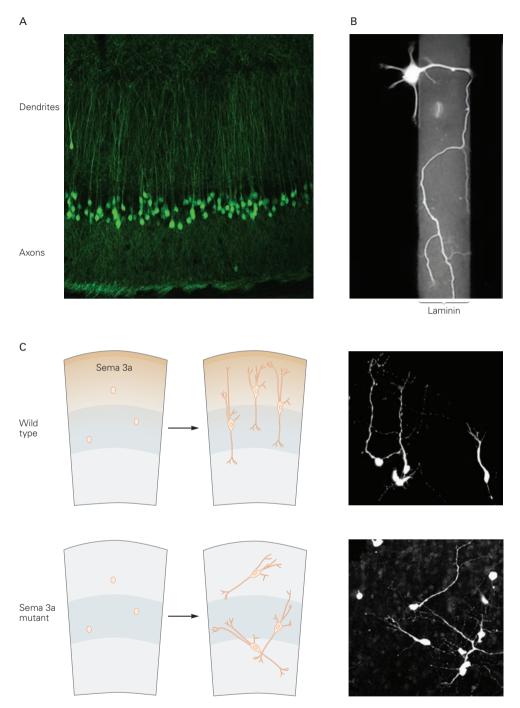

Figure 54–2 Extracellular factors determine whether neuronal processes become axons or dendrites.

A. Cortical pyramidal neurons in vivo display a common axonal and dendritic orientation. (Image reproduced, with permission, from Josh Sanes.)

B. Neurons growing on laminin acquire polarity. When a cortical neuron extends a process from a less attractive substrate onto laminin, the process grows faster and usually becomes an axon. (Image reproduced, with permission, from Paul Letourneau.)

C. In the developing neocortex semaphorin-3A (Sema 3A) is secreted by cells near the pial surface. Semaphorin-3A is an attractant for growing dendrites, helping to establish neuronal polarity and orientation. The parallel orientation of cortical pyramidal neurons is disrupted in mutant mice lacking functional semaphorin-3A. (Reproduced, with permission, from Polleux, Morrow, and Ghosh 2000.)

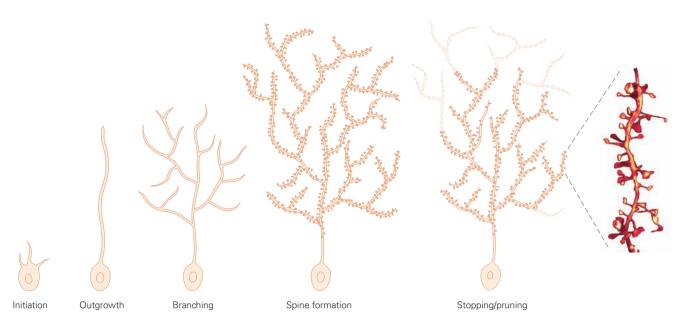

Figure 54–3 Dendritic branching develops in a series of steps. The outgrowth of dendrites involves the formation of elaborate branches from which spines develop. Certain

branches and spines are later pruned to achieve the mature pattern of dendrite arborization. (Image of spines at right reproduced, with permission, from Stefan W. Hell.)

neurons can be classified. Cerebellar Purkinje cells can be distinguished from granule cells, spinal motor neurons, and hippocampal pyramidal neurons simply by looking at the pattern of their dendrites.

How is dendritic pattern established? Neurons must have intrinsic information about their shape because the patterns in tissue culture are strikingly reminiscent of those in vivo (Figure 54–4). The transcriptional programs that specify neuronal subtype (see Chapter 52) presumably also encode information about neuronal shape. A second mechanism for establishing the pattern of dendritic arbors is the recognition of one dendrite by others of the same cell. In the *Drosophila* nervous system repellent signaling between dendrites of the same neuron, mediated by the different isoforms of a recognition protein known as DS-CAM, helps to ensure that dendrites expand over a broad territory rather than bunching together.

The dendrites of neighboring neurons also provide cues. In many cases the dendrites of a particular class of neuron cover a surface with minimal overlap, a spacing pattern called *tiling*. The tiling of dendrites appears to result from specific inhibitory interactions among the dendrites of a particular class of neuron. Tiling allows each class of neuron to receive information from the entire surface or area it innervates. Tiling of a region by the dendrites of one class of neuron also

avoids the confusion that could arise if the dendrites of many different neurons occupied the same area.

Thus interactions between dendrites establish an overall arborization pattern through a mixture of intrinsic and extracellular mechanisms. Once a cell process is committed to an axonal or dendritic character, it becomes sensitive to a variety of intrinsic and extrinsic signals that determine its trajectory. For dendrites these patterning signals determine neuronal morphology. For axons, which we consider next, the signals guide the axons to their targets.

The Growth Cone Is a Sensory Transducer and a Motor Structure

Once an axon forms it begins to grow toward its synaptic target. The key neuronal element responsible for axonal growth is a specialized structure at the tip of the axon called the *growth cone*. Both axons and dendrites use growth cones for elongation, but those linked to axons have been studied more intensively.

Ramón y Cajal discovered the growth cone and had the key insight that it was responsible for axonal pathfinding. With static images alone for inspiration (Figure 54–5A), he envisioned the growth cone to be "endowed with exquisite chemical sensitivity, rapid

Purkinje cell

Pyramidal cell

Figure 54-4 The morphologies of neurons are preserved in dissociated cell culture. Cerebellar Purkinie neurons and hippocampal pyramidal neurons have distinctive patterns of dendritic branching. These basic patterns are recapitulated when these two classes of neurons are isolated and grown in dissociated cell culture. (The image on the upper left is from David L. Becker; upper right from Yoshio Hirabayashi; lower left by Grazyna Gorney, reproduced, with permission, from Terry E. Robinson; the image in the lower right from Kelsey Martin. All images reproduced with permission.)

ameboid movements and a certain motive force, thanks to which it is able to proceed forward and overcome obstacles met in its way ... until it reaches its destination."

Many studies over the past century have confirmed Ramón y Cajal's intuition. We now know that the growth cone is both a sensory structure that receives directional cues from the environment and a motor structure whose activity drives axon elongation. Ramón y Cajal also pondered "what mysterious forces precede the appearance of these processes ... promote their growth and ramification ... and finally establish those protoplasmic kisses ... which seem to constitute the final ecstasy of an epic love story." In more modern and prosaic terms we now know that the growth cone guides the axon by transducing positive and negative cues into signals that regulate the cytoskeleton, thereby determining the course and rate of axonal outgrowth.

Growth cones have three main compartments. Their *central core* is rich in microtubules, mitochondria, and other organelles. Long slender extensions called

filopodia project from the body of the growth cone. Between the filopodia lie *lamellipodia*, which are also motile and give the growth cone its characteristic ruffled appearance (Figure 54–5C).

Growth cones sense environmental signals through their filopodia: rod-like, actin-rich, membrane-limited structures that are highly motile. Their surface membranes bear receptors for the molecules that serve as directional cues for the axon. Their length—tens of micrometers in some cases—permits the filopodia to sample environments far in advance of the central core of the growth core. Their rapid movements permit them to compile a detailed inventory of the environment, and their flexibility permits them to navigate around cells and other obstacles.

When filopodia encounter signals in the environment, the growth cone is stimulated to advance, retract, or turn. Several motors power these orienting behaviors. One source of power is the movement of actin along myosin, an interaction similar to the one

that powers the contraction of skeletal muscle fibers, although the actin and myosin of neurons are different from those in muscle. The assembly of actin monomers into polymeric filaments also contributes a propulsive force for filopodial extension. Acting in parallel, actin filaments constantly depolymerize at the base of filopodia. Depolymerization slows during periods of

growth cone advance, leading to greater net forward motion. The movement of membranes along the substrate provides yet another source of forward motion.

The contribution of each type of molecular motor to the advance of the growth cone is likely to vary from one situation to another. With all of these motors the final step involves the flow of microtubules from the

Figure 54–5 Neuronal growth cones.

electron microscopy. (Reproduced, with permission, from Bridgman and Dailey 1989.)

D. The growth cone of a neuron from *Aplysia* in which actin and tubulin have been visualized. Actin (purple) is concentrated in lamellipodia and filopodia, whereas tubulin and microtubules (aquamarine) are concentrated in the central core. (Image reproduced, with permission, from Paul Forscher and Dylan Burnette.)

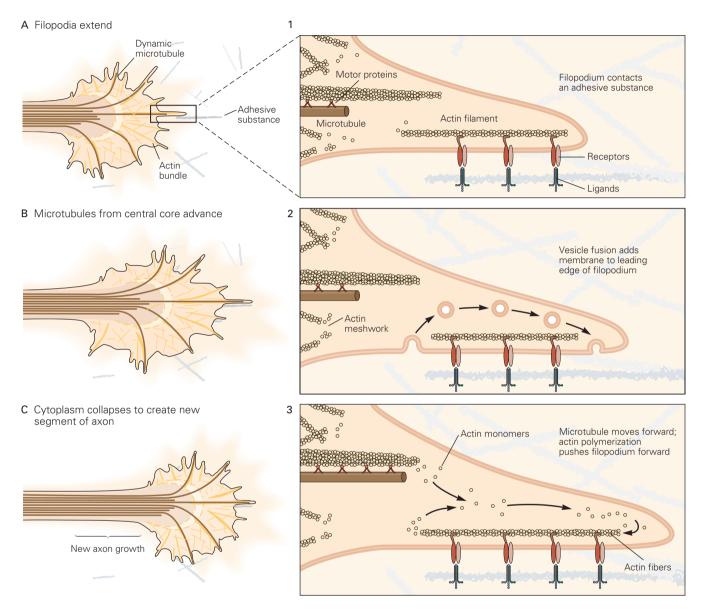

Figure 54–6 The growth cone advances under the control of cellular motors. (Modified, with permission, from Heidmann 1996.)

A. A filopodium contacts an adhesive cue and contracts, thus pulling the growth cone forward (1). Actin filaments assemble at the leading edge of a filopodium, disassemble at the trailing edge, and interact with myosin along the way (2). Actin polymerization pushes the filopodium forward (3). Force generated by the retrograde flow of actin pushes the filopodium forward. Exocytosis adds membrane to the leading edge of the filopo-

dium and supplies new adhesion receptors to maintain traction. Membrane is recovered at the back of the filopodium. The actin polymer is linked to adhesion molecules on the plasma membrane.

B. The combined action of these motors creates an actindepleted space that is filled by the advance of microtubules from the central core.

C. Individual microtubules condense to form a thick bundle, and the cytoplasm collapses around them to create a new segment of axonal shaft.

central core of the growth cone into the newly extended tip, thus moving the growth cone ahead and leaving in its wake a new segment of axon. New lamellipodia and filopodia form in the advancing growth cone and the cycle repeats (Figure 54–6).

Accurate pathfinding can occur only if the growth cone's motor action is linked to its sensory function. It is crucial therefore that the recognition proteins on the filopodia are signal-inducing receptors and not merely binding moieties that mediate adhesion. The binding of a ligand to its receptor affects growth in diverse ways. It stimulates the formation, accumulation, and even the breakdown of soluble intracellular molecules that function as second messengers. These second messengers affect the organization of the cytoskeleton, and in this way regulate the direction and rate of movement of the growth cone.

One important second messenger is calcium. The calcium concentration in growth cones is regulated by the activation of receptors on filopodia and this affects the organization of the cytoskeleton, which in turn modulates motility. Growth cone motility is optimal within a narrow range of calcium concentrations, called a *set point*. Activation of filopodia on one side of the growth cone leads to a concentration gradient of calcium across the growth cone, providing a possible basis for changes in the direction of growth.

Other second messengers that link receptors and motor molecules include cyclic nucleotides. These nucleotide second messengers modulate the activity of enzymes such as protein kinases, protein phosphatases, and rho-family guanosine triphosphatases (GTPases). In turn these messengers and enzymes regulate the activity of proteins that regulate the polymerization and depolymerization of actin filaments, thereby promoting or inhibiting axonal extension.

The critical role of intracellular signals in growth cone motility and orientation can be demonstrated using embryonic neurons grown in culture. Application of growth factors to one side of a growth cone activates receptors locally and leads to extension and turning of the growth cone toward the source of the signal. In essence, the factor attracts the growth cone. Yet when cyclic adenosine monophosphate (cAMP), levels in the neuron are decreased, the same stimulus acts as a repellent and the growth cone turns away from the signal (Figure 54–7). Other repulsive factors can become attractive when levels of the second messenger cyclic guanosine 3'-5'-monophosphate (cGMP) are raised.

Another strategy for coupling the sensory and motor functions of the growth cone is to engage the cytoskeleton directly, through the intracellular domain of receptors. Integrin receptors couple to actin in growth cones when they bind molecules associated with the surface of adjoining cells or the extracellular matrix, thereby influencing motility. Recently, it has been found that growth cones contain messenger RNAs as well as the machinery for protein synthesis. The activation of receptors can lead to local synthesis of new motor proteins precisely when and where they are needed. Thus the growth cone has many strategies

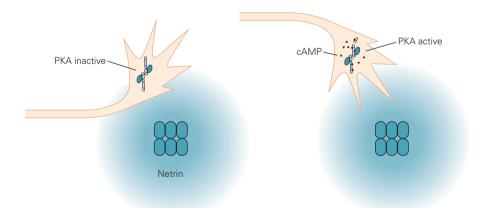

Figure 54–7 Changes in the level of intracellular regulatory proteins can determine whether the same extrinsic cue attracts or repels the growth cone. The state of protein kinase A (PKA) activity can alter the growth cone's response to an extracellular orienting factor, in this instance the protein netrin.

When PKA activity and intracellular cAMP levels are low, the growth cone is repelled by netrin. When PKA activity is high, the resulting elevation in intracellular cAMP causes the growth cone to be attracted to a local source of netrin. (Adapted, with permission, from Ming et al. 1997.)

and mechanisms for integrating molecular signals to direct the axon in specific directions.

Molecular Cues Guide Axons to Their Targets

For much of the 20th century a debate raged between advocates of two very different views of how growth cones navigate embryonic terrains to reach their targets. A molecular view of axonal guidance was first articulated at the turn of the 20th century by the physiologist J. N. Langley. But by the 1930s many eminent biologists, including Paul Weiss, believed that axonal outgrowth was essentially random and that appropriate connections persisted largely because of productive, matching patterns of electrical activity in the axon and its target cell.

In our molecular age Weiss's ideas may seem simplistic but they were not unreasonable at the time. In tissue culture axons grow preferentially along mechanical discontinuities (scratches and bumps on a cover slip), and embryonic nerve trunks often align themselves with solid supports (blood vessels or cartilage). It seemed logical to Weiss that mechanical guidance, called stereotropism, could account for axonal patterning. We are quite comfortable today with the idea that electrical signals can be used to change the way current flows in a computer without the need to resolder connections. Likewise, patterns of activity and experience can strengthen or weaken neural connections without requiring the formation of new axonal pathways. Then why not consider that congruent activity, called resonance by Weiss, is involved in establishing appropriate connections?

Today few scientists believe that stereotaxis or resonance are crucial forces in neuronal connectivity. The tipping point that shifted opinion in favor of the molecular view was an experiment performed with frogs and other amphibia in the 1940s by Roger Sperry (ironically, a student of Weiss). Sperry manipulated the information carried from the eye to the brain by the axons of retinal ganglion cells. These axons terminate in their target areas—the lateral geniculate body in the thalamus and the superior colliculus (or optic tectum) in the midbrain—in such a way that an orderly retinotropic map of the visual field is created.

Because of the optics of the eye, the visual image on the retina is an inversion of the visual field. The retinal ganglion cells reinvert the image by the manner in which their axons terminate in the optic tectum, the main visual center in the brain of frogs (Figure 54–8A). If the optic nerve is cut the animal is blinded. In lower vertebrates cut retinal axons can reestablish projections to the tectum, whereupon vision is restored. This is not the case in mammals, as we will discuss in Chapter 57.

Sperry performed a simple yet profound experiment that demonstrated the organization of the retinotectal projection. He severed the optic nerve in a frog and then rotated the eye in its socket by 180 degrees before regeneration of the nerve. Remarkably, the frog exhibited orderly responses to visual input, but the behavior was wrong. When the frog was presented with a fly on the ground it jumped up, and when offered a fly above its head it struck downward (Figure 54–8B). Importantly, the animal never learned to correct its mistakes. Sperry suggested—and later verified with anatomical and physiological methods that the retinal axons had reinnervated their original tectal targets, even though these connections provided the brain with erroneous spatial information that led to aberrant behavior. The inference of these experiments was that recognition between axons and their targets relied on molecular matching rather than functional validation and refinement of random connections.

But Weiss's ideas are by no means obsolete. Indeed, we now recognize that the activity of neural circuits can play a crucial role in shaping connectivity. The current view is that molecular matching predominates during embryonic development, and that activity and experience modify circuits after they have formed. In this chapter and the next we describe the molecular cues that guide the formation of neural connections, and then in Chapter 56 we examine the role of activity and experience in the fine-tuning of synaptic connections.

Sperry's conjecture, often called the chemospecificity hypothesis, prompted developmental neurobiologists to search for axonal and synaptic "recognition molecules." Success was limited for the first few decades, in part because these molecules are present in small amounts and on discrete subsets of neurons and there were no effective methods for isolating rare molecules from complex tissues. As with the search for neural inducers, advances in biochemical and molecular biological methods gradually made this task more feasible, and many proteins involved in the guidance of axons to their targets have now been discovered. These proteins typically consist of pairs of ligands and receptors: The ligands are presented by cells along the pathway an axon follows and the receptors by the growth cone itself.

In the most general terms, guidance cues can be presented on cell surfaces, in the extracellular matrix, or in soluble form. They act by either promoting or inhibiting outgrowth of the axon. Most receptors are embedded in

Figure 54–8 Roger Sperry's classical experiments on regeneration in the visual system provided evidence for chemoaffinity in the wiring of connections.

A. In the visual system of the frog the lens projects an inverted visual image onto the retina and the optic nerve then transfers the image, with an additional inversion, to the optic tectum. The orderly arrangement of inputs to the tectum is responsible for this transfer. Neurons in the anterior retina project axons to the posterior tectum, while neurons in the posterior retina project to the anterior tectum. Similarly, neurons in the dorsal retina project to the ventral tectum and neurons in the ventral retina

project to the dorsal tectum. As a result, visually guided behaviors (here catching a fly) are accurate. (A, anterior; D, dorsal; P, posterior; V, ventral.)

B. If the optic nerve is cut, and the eye is surgically rotated in its socket before the nerve regenerates, visually guided behavior is aberrant. When a fly is presented overhead, the frog perceives it as below, and vice versa. The inversion of behavioral reflexes results from the connection of regenerating retinal axons to their original targets, even though these connections now transfer an inverted, inappropriate map of the world into the brain.

the growth cone membrane; they have an extracellular domain that selectively binds the cognate ligand and an intracellular domain that couples to the cytoskeleton, either directly or through intermediates such as second messengers. Activation of these receptors can promote or inhibit neurite outgrowth. A ligand presented to one side of the growth cone can result in turning. In this way

the local distribution of environmental cues can steer the growth cone.

As a result of these recent discoveries, axon guidance—a process that appeared mysterious years ago—can now be viewed as the orderly consequence of protein-protein interactions that instruct the growth cone to grow, turn, and stop (Figures 54–9 and 54–10).

1 Extracellular matrix adhesion 2 Cell surface adhesion 3 Fasciculation Pioneer neuron 4 Chemoattraction 5 Contact inhibition 6 Chemorepulsion

Figure 54–9 Extracellular cues use a variety of mechanisms to guide growth cones. The axon can interact with growth-promoting molecules in the extracellular matrix (1). It can interact with adhesive cell-surface molecules on neural cells (2). The growing axon can encounter another axon from a

"pioneer" neuron and track along it, a process termed fasciculation (3). Soluble chemical signals can attract the growing axon to its cellular source (4). Intermediate target cells that express cell-surface repellent cues can cause the axon to turn away (5). Soluble chemical signals can repel the growing axon (6).

This limited set of instructions is sufficient, when presented with spatial precision, to choreograph growth cone behaviors with exquisite subtlety. Axonal guidance can therefore be explained by describing how and where ligands are presented and how the growth cone integrates this information to generate an orderly response. In the rest of the chapter we illustrate lessons learned by describing the journeys of two types of axons: the axons of retinal ganglion neurons and those of a particular class of sensory relay neurons in the spinal cord.

The Growth of Retinal Ganglion Axons Is Oriented in a Series of Discrete Steps

Sperry's experiment implied the existence of axon guidance cues but did not reveal where they were or how they worked. For a time, one prominent view was that recognition occurred mostly at or near the target and that mechanical forces or long-range chemotactic factors sufficed to get axons to the vicinity of the target.

We now know that axons reach distant targets in a series of discrete steps, making frequent decisions at closely spaced intervals along their route. To illustrate this point we shall trace in greater detail the path that Sperry was trying to understand, that of a retinal axon growing to the optic tectum.

Growth Cones Diverge at the Optic Chiasm

The first task of the axon of a retinal ganglion cell is to leave the retina. As it enters the optic fiber layer it extends along the basal lamina and glial end-feet positioned at the retina's edge. The growth of the axon is oriented from the outset, indicating that it can read directional cues in the environment. As it approaches the center of the retina it comes under the influence of attractants emanating from the optic nerve head (the junction of the optic nerve with the retina proper), which guide it into the optic stalk. It then follows the optic nerve toward the brain (Figure 54–11).

The first axons to travel this route follow the cells of the optic stalk, the rudiment of the neural tube that connects the retina to the diencephalon from which it arose. These "pioneer" axons then serve as scaffolds for later-arriving axons, which are able to extend accurately simply by following their predecessors (see strategy 3 in Figure 54–9). Once they reach the optic chiasm, however, the retinal axons must make a choice. Axons that arise from neurons in the nasal hemiretina of each eye cross the chiasm and proceed to the opposite side of the brain, whereas those from the temporal half are deflected as they reach the chiasm and so stay on the same side of the brain (Figure 54–12A).

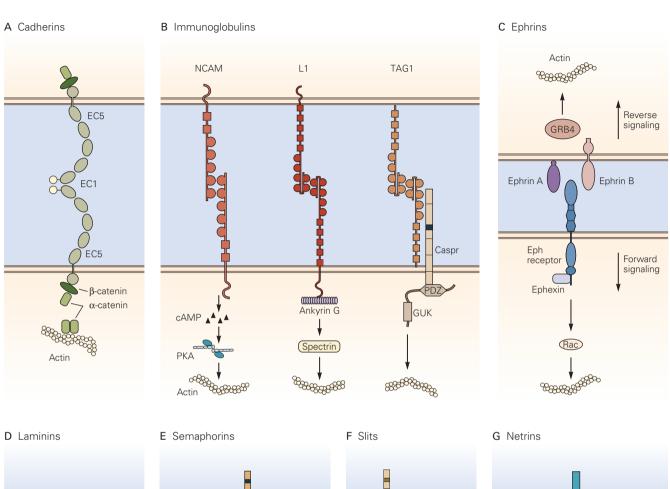

This divergence in trajectory reflects the differential responses of axons from the nasal and temporal hemiretinas to guidance cues presented by midline chiasm cells. Some retinal axons contact and traverse chiasm cells, whereas others are inhibited by these cells and deflected away, thus remaining in the ipsilateral side. One of the key molecules presented by chiasm cells is a membrane-bound repellent of the ephrin-B family (Figure 54–12B), which also figures in later steps of retinal ganglion cell axon guidance.

The fraction of temporal retinal axons that project ipsilaterally varies among species: a few in lower vertebrates, some in rodents, and many in humans. These differences reflect placement of the eyes. In many animals the eyes point to the sides and monitor different parts of the visual world, so that information from the two eyes need not be combined. In humans both eyes look forward and sample largely overlapping regions of the visual world, so coordination of visual input is essential.

After crossing the optic chiasm, retinal axons assemble in the optic tract along the ventral surface of the diencephalon. Axons then leave the tract at different points. In most vertebrate species the tectum of the midbrain (called the superior colliculus in mammals) is the major target of retinal axons, but a small number of axons project to the lateral geniculate nucleus of the thalamus. In humans, however, most axons project to the lateral geniculate, a sizable number reach the colliculus, and small numbers project to the pulvinar, superchiasmatic nucleus, and pretectal nuclei. Within these targets different retinal axons project to different regions. As Sperry showed, the retinal axons form a precise retinotopic map on the tectal surface. Similar maps form in other areas innervated by retinal axons.

Having reached an appropriate position within the tectum, retinal axons need to find an appropriate synaptic partner. To achieve this last leg of their journey, retinal axons turn and dive into the tectal neuropil (Figure 54–11), descending along the surface of radial glial cells, which provide a scaffold for radial axonal growth. Although radial glial cells span the entire extent of the neuroepithelium, each retinal axon confines its synaptic terminals to a single layer. The dendrites of many postsynaptic cells extend through multiple layers and form synapses along their whole length, but retinal inputs are restricted to a small fraction of the target neuron's dendritic tree. These organizational features imply that layer-specific cues arrest axonal elongation and trigger arborization.

Axons therefore solve the problem of longdistance navigation by dividing their journey into short segments, and by recognizing and responding to

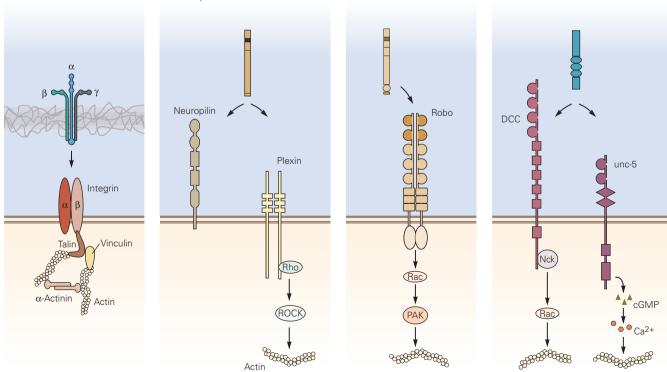

Figure 54–10 (Opposite) Diverse molecular families control the growth and guidance of developing axons.

- A. A large family of classical cadherins promote cell and axonal adhesion, primarily through homophilic interactions between cadherin molecules on adjacent neurons. Adhesive interactions are mediated through interactions of the extracellular EC1 domains. Cadherins transduce adhesive interactions though their cytoplasmic interactions with catenins, which link cadherins to the actin cytoskeleton.
- B. A diverse array of immunoglobulin superfamily proteins are expressed in the nervous system and mediate adhesive interactions. The three examples shown here, NCAM, L1, and TAG1, can bind both homophilically and heterophilically to promote axon outgrowth and adhesion. These proteins contain both immunoglobulin domains (circles) and fibronectin type III domains (squares). Homophilic interactions typically involve amino terminal immunoglobulin domains. Different Ig adhesion molecules interact with the cytoskeleton via diverse cytoplasmic mediators, only a few of which are shown here.
- C. Different ephrin proteins bind to Eph class tyrosine kinase receptors. Class A ephrins are linked to the surface membrane through a glycosyl phosphatidylinositol tether, whereas class B ephrins are transmembrane proteins. Class A ephrins typically bind class A Eph kinases, and class B ephrins typically bind class B Eph kinases. Forward Eph signaling usually elicits

- repellant or inhibitory responses in receptive cells, whereas reverse ephrin signaling can elicit adhesive or inhibitory responses. Ephrin and Eph signaling involves many different cytoplasmic mediators.
- D. Laminin proteins are bound to the extracellular matrix and promote cell adhesion and axon extension through interactions with integrin receptors. Integrins mediate adhesion and axon growth through interactions with the cytoskeleton via many intermediary proteins.
- E. Semaphorin proteins can promote or inhibit axonal growth through interaction with a diverse array of plexin and neuropilin receptors, which transduce signals via rho class GTPases and downstream kinases.
- F. Slit proteins typically mediate repellant responses through interaction with Robo class receptors, which influence axonal growth via intermediary GTPases such as Rac.
- G. The secreted- or extracellular-matrix-associated netrin proteins mediate both chemoattractant and chemorepellent responses. Attractant responses are mediated through interaction with DCC (deleted in colorectal cancer) receptors, whereas repellent responses involve interactions with DCC and unc-5 co-receptors. Netrin receptors signal via GTPases and cGMP cascades.

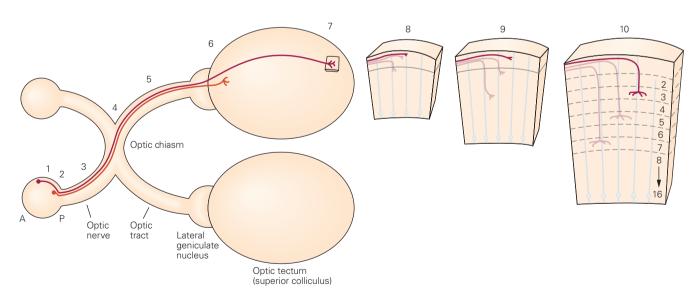

Figure 54–11 The axons of retinal ganglion cells grow to the optic tectum in discrete steps. Two neurons that carry information from the nasal half of the retina are shown. The axon of one crosses the optic chiasm to reach the contralateral optic tectum. The axon of the other also crosses the optic chiasm but projects to the lateral geniculate nucleus. The numbers indicate important landmarks on the axon's journey. The growing axon is directed toward the optic nerve head with the retina

(1), enters into the optic nerve (2), extends through the optic nerve (3), swerves to remain ipsilateral (not shown) or cross to the contralateral side at the optic chiasm (4), extends through the optic tract (5), enters into the optic tectum or lateral geniculate nucleus (6), navigates to an appropriate rostrocaudal and dorsoventral position on the tectum (7), descends from the tectal surface (8), stops at an appropriate layer where a rudimentary terminal arbor is formed (9), and finally is refined (10).

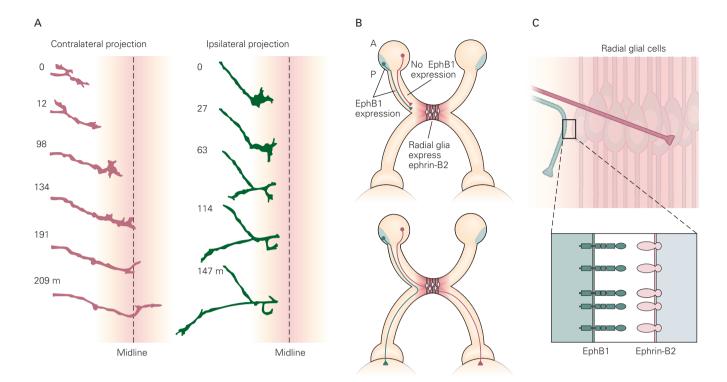

Figure 54–12 Axons of retinal ganglion neurons diverge as they reach the optic chiasm.

A. A time lapse series shows axons approaching the midline. Axons that arise from the nasal hemiretina cross the optic chiasm and project to the contralateral tectum (left). In contrast axons from the temporal hemiretina reach the chiasm but fail to cross and thus project toward the ipsilateral tectum (right). (Reproduced, with permission, from Godemont, Wong, and Mason 1994.)

B. The axons of temporal hemiretina neurons, which express the tyrosine kinase receptor EphB1, encounter ephrin-B2 expressed by midline radial glial cells at the optic chiasm and so are prevented from crossing the midline. The axons of nasal hemiretina neurons, which lack EphB1 receptors, are unaffected by the presence of ephrin-B2 and cross to the contralateral side. (A, anterior; P, posterior.)

C. Higher-power view illustrating the trajectories of retinal ganglion cell axons at the chiasm.

intermediate targets along the path to their final targets. Some intermediate targets, such as the optic chiasm, are "decision" regions where axons need to diverge.

Reliance on intermediate targets is an effective solution to the problem of long-distance axonal navigation but is not the only one. In some cases the first axons reach their targets when the embryo is small and the distance to be covered is short. These "pioneer" axons respond to molecular cues embedded in cells or the extracellular matrix along their way. The first axons to exit the retina fall within this class. Axons that appear later, when distances are longer and obstacles more numerous, can reach their targets by following the pioneers. Yet another guidance mechanism is a molecular gradient. Indeed, as we will see, gradients of cell-surface molecules in the tectum inform axons about their proper termination zone.

Ephrins Provide Gradients of Inhibitory Signals in the Brain

So far we have seen how retinal axons reach the tectum by responding to a series of discrete directional cues. However, these choices during growth do not account for the smoothly graded connections implied by Sperry's analysis of the retinotopic map in the tectum. The quest for the hypothetical "graded map molecules" became a major focus for developmental neurobiologists, and so we describe it in some detail.

A key breakthrough in the quest for these molecules came with the development of bioassays in which explants from defined portions of the retina were laid on substrates of tectal membrane fragments. The membrane fragments were taken from defined anteroposterior portions of the tectum and arranged

in alternating stripes. Axons from the temporal (posterior) hemiretina were found to grow preferentially on membranes from anterior tectum, a preference similar to that exhibited in vivo (Figure 54–13). This preference was found to result from the presence of inhibitory factors in posterior membranes rather than from attractive or adhesive substances in anterior membranes. This observation was one of the first to emphasize the role of inhibitory or repellent substances in axon guidance.

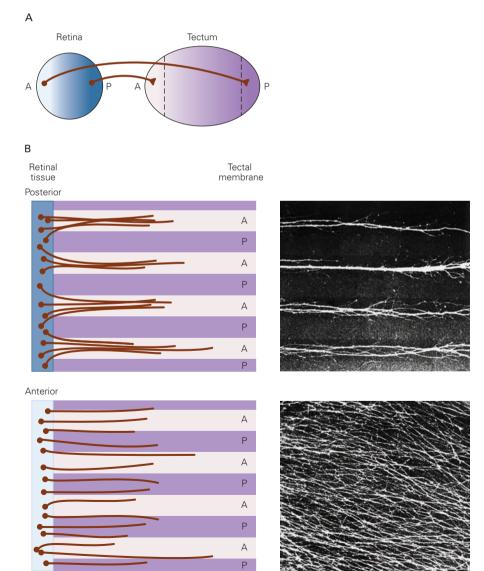

This stripe assay permitted the characterization of an inhibitory cue, present in membranes from the posterior but not the anterior tectum. Independently, molecular biologists identified a family of receptor tyrosine kinases, the Eph kinases, and a large family of membrane-associated ligands, the ephrins. Both receptors and ligands are divided into A and B subfamilies. The ephrin-A proteins bind and activate EphA kinases; conversely, ephrin-B proteins bind and activate EphB kinases (Figure 54–14).

The two lines of research converged when the tectal inhibitory cue was identified as ephrin-A5. We now know that the Eph kinases and ephrins serve many functions in neural and nonneural tissues and that each class of proteins can serve as ligands or receptors, depending on cellular context. In the developing nervous system these proteins comprise a major group of repellent signals.

Figure 54–13 Repellant signals guide developing retinal axons in vitro.

A. Retinal ganglion axons from the posterior (temporal) hemiretina project into the anterior developing tectum. Conversely, axons from the anterior (nasal) hemiretina project into the posterior tectum.

B. Fragments of membrane were taken from specified anteroposterior portions of the tectum and arranged in alternating strips. Axons from explants of posterior retina grow selectively on the fragments from anterior tectum. The preferential growth of axons on anterior membrane results from an inhibitory cue in the posterior membrane. In contrast, axons from anterior retina grow on both anterior and posterior tectal membrane fragments. (A, anterior; P, posterior.) (Modified, with permission, from Walter, Henke-Fahle, and Bonhoeffer 1987)

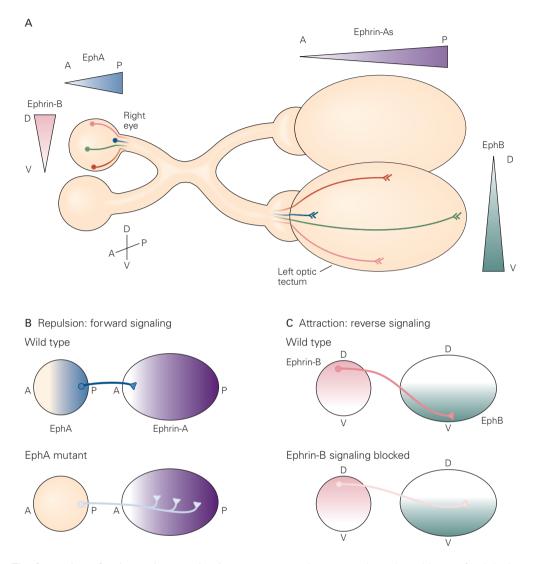

Figure 54–14 The formation of retinotopic maps in vivo depends on ephrin-Eph kinase signaling.

A. In the retina EphA receptors are expressed in an anteroposterior (A-P) gradient, and ephrin-B is expressed in a dorsoventral (D-V) gradient. In the tectum ephrin-A receptors are distributed in an anteroposterior gradient and EphB in a dorsoventral gradient.

B. Expression of EphA in retinal axons that derive from neurons in the posterior (temporal) retina directs axon growth to the

anterior tectum through avoidance of ephrin-A proteins. In EphA mutant mice posterior retinal axons are able to project to a more posterior domain within the tectum.

C. EphB signaling directs the projection of dorsal retinal axons to the ventral tectum. Blocking ephrin-B signaling with soluble EphB protein causes dorsal axons to project to an abnormally dorsal domain within the tectum.

Ephrin-Eph interactions account for formation of the retinotopic map in the tectum. In the tectum ephrin-A2 and ephrin-A5 levels are graded along the anteroposterior axis, and in the retina the levels of the Eph receptors are also graded along the anteroposterior axis. These gradients run in opposite directions in the tectum: ephrin-A grades from anterior-low to

posterior-high and in the retina Eph-A kinase from posterior-high to anterior-low (Figure 54–14A). Such counter-gradients account, at least in part, for topographic mapping. Axons from posterior retinal ganglion cells with high levels of receptors are repelled most strongly by the high level of ephrin-A in the posterior tectum and thus are confined to the anterior

tectum. The less sensitive axons from the anterior retina are able to penetrate further into the posterior domain of the tectum. Ephrin-A2 and -A5 are therefore strong candidates for chemospecificity factors of the type postulated by Sperry.

The crucial role of ephrins and Eph kinases in the formation of retinotopic maps has been confirmed in vivo. Overexpression of ephrin-A2 in the developing optic tectum of chick embryos generates small patches of cells in the rostral tectum that are abnormally rich in ephrin-A2. Temporal retinal axons, which normally avoid the ephrin-rich caudal tectum, also avoid these patches in the rostral tectum, and they terminate in abnormal positions. In contrast, nasal retinal axons, which normally grow toward the caudal tectum, are not perturbed by encounters with excess ephrin.

Conversely, in mice with targeted mutations in the *ephrin-A2* and *ephrin-A5* genes some posterior retinal axons terminate in inappropriately posterior tectal regions (Figure 54–14B). Anterior retinal axons, which naturally express low levels of EphA proteins, project normally in these mutants. In mice lacking both ephrin-A proteins these deficits are more severe than with either single mutant. Thus the interaction of ephrin-A with EphA receptors is crucial for the targeting of retinal axons in the tectum. These ephrin/EphA pairs possess the properties of the recognition molecules that Sperry predicted were necessary to direct topographic mapping along the anteroposterior axis of the tectum.

But the retinal map is two-dimensional, so what establishes order along the dorsoventral axis? The ephrin/EphB pairs are involved in establishing this axis. Just as ephrin-A and EphA are graded along the anteroposterior axis, ephrin-B and EphB are graded along the dorsoventral axis, and genetic manipulation of ephrin-B and EphB levels affects dorsoventral mapping (Figure 54–14C). Thus the retinotopic map is arranged along rectangular coordinates with ephrin/EphA and ephrin/EphB labeling the anteroposterior and dorsoventral axes, respectively.

This simple view is satisfying, but the reality is more complex. First, Eph kinases are expressed in the tectum as well as in the retina, and ephrins are expressed in the retina as well as in the tectum. Thus, so-called "cis" interactions (Eph and ephrin on the same cell) as well as "trans" interactions (Eph on growth cone, ephrin on target cell) may be involved. Second, both ligands and receptors are present at multiple points along the optic pathway and play multiple roles. As we have seen, ephrin/EphB interactions affect not only dorsoventral mapping but also the decision of an axon to cross to the contralateral side at the optic chiasm. Finally, in

visual circuits precise axonal mapping is regulated by patterns of neural activity, as discussed in the next two chapters. Nonetheless, we now have the initial outline of a molecular strategy for the formation of specific topographic projections from the eye to the brain.

Axons from Some Spinal Neurons Cross the Midline

One of the fundamental features of the central nervous system is the need to coordinate activity on both sides of the body. To accomplish this task certain axons need to project to the opposite side.

We have seen one example of axonal crossing in the optic chiasm. Another example that has been studied in detail is the axonal crossing of *commissural neurons* that convey sensory information from the spinal cord to the brain at the ventral midline of the spinal cord across the floor plate. After crossing, axons turn abruptly and grow up toward the brain. This simple trajectory raises several questions. How do these axons reach the ventral midline? On arrival how do they cross the midline? After crossing how do they *ignore* cues that axons on the other side are using to get to the midline? In other words, why do they turn toward the brain instead of crossing back?

Netrins Direct Developing Commissural Axons Across the Midline

Many of the neurons that send axons across the ventral midline are generated in the dorsal half of the spinal cord. The first task for these axons is to reach the ventral midline. Ramón y Cajal considered the possibility that chemotactic factors emitted by targets could attract axons, but this idea lay dormant for nearly a century. We now know that such chemotropic factors do exist and one of them, the protein netrin-1, mediates the chemoattractant activity of the floor plate. When presented in culture, netrin attracts commissural axons; when mice are deprived of netrin-1 function, axons fail to reach the floor plate (Figure 54–15).

The netrin protein is structurally related to the protein product of *unc-6*, a gene shown to regulate axon guidance in the nematode *C. elegans*. Two other *C. elegans* genes, *unc-5* and *unc-40*, encode receptors for the unc-6 protein. Vertebrate netrin receptors are related to the unc-5 and unc-40 receptors: The unc-5H proteins are homologs of unc-5, and DCC (deleted in colorectal cancer) and neurogenin are related to unc-40 (see Figure 54–10G). These receptors are members of the immunoglobulin superfamily, and their functions have

Figure 54–15 Netrin signaling attracts the axons of spinal commissural neurons to the floor plate. (Micrographs reproduced,

the floor plate (FP) at the ventral midline of

B. Most commissural axons fail to reach and cross the floor plate when netrin or DCC

the spinal cord.

proteins are eliminated.

been remarkably conserved throughout animal evolution (Figure 54–16). This conservation supports the use of simple and genetically accessible invertebrates to unravel developmental complexities. In no area has this approach been more fruitful than in the analysis of axon guidance. Dozens of genes that affect this process

were first identified and cloned in Drosophila and C. elegans and then shown to play important and related roles in mammals.

Other signaling systems work with netrins to guide commissural axons on this initial phase of their journey to the brain. For example, bone morphogenetic proteins secreted by the roof plate act as repellants and begin to direct commissural axons ventrally.

Chemoattractant and Chemorepellent Factors Pattern the Midline

Once commissural axons reach the midline, they find themselves exposed to the highest available level of netrin-1. Yet this netrin-rich environment does not keep the axons at the midline indefinitely. Instead they cross to the other side of the spinal cord, while at the same time their contralateral counterparts are navigating up the netrin chemoattractant gradient.

This puzzling behavior is explained by the fact that growth cones change their responsiveness to attractive and repellent signals as a consequence of exposure to floor plate signals. This switch illustrates an important property of intermediate targets involved in axon guidance. Factors presented by intermediate targets not only influence the growth of axons but also change the sensitivity of the growth cone, preparing it for the next leg of its journey.

Once axons arrive at the floor plate, they become sensitive to the chemorepellent signal slit, which is secreted by floor plate cells (Figure 54–17). Before commissural axons reach the floor plate the robo proteins that serve as slit receptors are kept inactive by expression of a related protein, rig-1. As axons reach the floor plate rig-1 is lost, unleashing robo activity and causing axons to respond to the repellant actions of slit. This repellant action propels growth cones *down* the slit gradient into the contralateral side of the spinal cord. In addition, activated robo forms a complex with

DCC, which renders these netrin receptors incapable of responding to their ligand. The decreased sensitivity of growth cones to the attractive properties of the floor plate helps to account for the transient nature of the floor plate's influence on axons.

Finally, once axons have left the floor plate they turn rostrally toward their eventual synaptic targets in the brain. A rostrocaudal gradient of Wnt proteins expressed by floor plate cells appears to direct axon growth rostrally at the ventral midline (Figure 54–17D). Thus different cues guide commissural axons during distinct phases of their overall trajectory. This same process is presumably played out for hundreds and even thousands of classes of neurons to establish the mature pattern of brain wiring.

An Overall View

Many developmental processes shape precise patterns of connections in the nervous system, but none is more important than the guidance of axons from their origin to appropriate targets. The specificity required to achieve the correct wiring is extraordinary. Axons need to grow long distances, bypassing numerous targets along the way, before reaching and forming connections with appropriate synaptic partners.

The nervous system has devised elaborate mechanisms to achieve its basic wiring plan. At the cellular level one basic strategy is to break the long journey into manageable legs. Thus axons do not set off like explorers of old, crossing completely uncharted territory in search of distant goals. Instead, they receive guidance

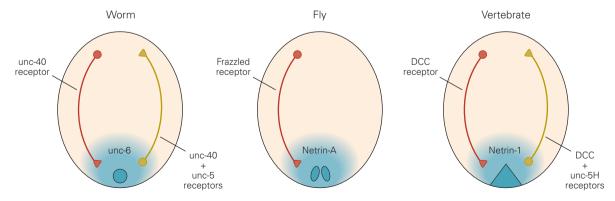

Figure 54–16 The expression and activity of netrins have been conserved throughout evolution. Netrins are secreted by ventral midline cells in worms, flies, and vertebrates and interact with receptors on cells or axons that migrate or extend

along the dorsoventral axis. The netrin receptors unc-40 (worm), frazzled (fly), and deleted in colorectal cancer (DCC) (vertebrate) mediate netrin's attractant activity, whereas unc-5 class receptors mediate its repellent activity.

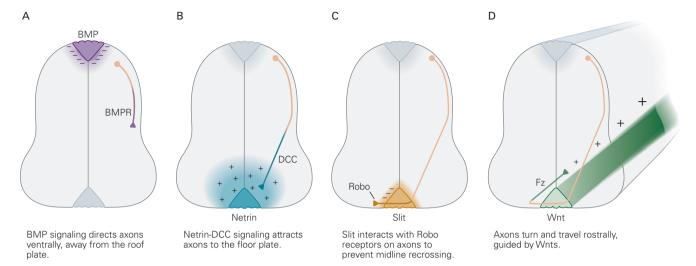

Figure 54–17 Guidance cues expressed by roof plate and floor plate cells guide commissural axons in the developing spinal cord.

- **A.** Bone morphogenetic proteins (**BMP**) secreted by roof plate cells interact with BMP receptors on commissural axons to direct the axons away from the roof plate.
- **B.** Netrin expressed by floor plate cells attracts commissural axons to the ventral midline of the spinal cord. Sonic hedgehog has also been implicated in the ventral guidance of commissural axons.
- C. Slit proteins secreted by floor plate cells interact with robo receptors on commissural axons to prevent these axons from

recrossing the midline. Prior to crossing, but not after, commissural axons express robo3 (rig-1) in addition to robo1 and robo2. The rig-1 protein inactivates the robo receptors, preventing the axons from responding to the repellant effects of slits as they approach the ventral midline.

D. Wnt proteins secreted from floor plate cells and distributed in a rostrocaudal gradient interact with frizzled (Fz) proteins on commissural axons after midline crossing, guiding them toward the brain.

at intervals along the way. Some axons that grow early in the embryo, when distances are short, serve as scaffolds for later-growing axons. Other axons grow along epithelial surfaces or extracellular matrices. Often so-called guidepost cells or intermediate targets mark sites at which axons need to make divergent choices.

The axon receives and responds to these guidance clues with a specialized terminal apparatus, the growth cone. The growth cone is both a sensory and a motor structure. It bears numerous receptors that bind environmental cues as well as cytoskeletal proteins and actin-based motors that propel it forward. And it contains signal transduction systems that convert ligand-receptor binding into instructions that steer the growth cone.

In the past several years rapid progress has been made in the identification of molecules that guide axons. Guidance cues include soluble, membrane-bound, and extracellular matrix molecules. Many of the soluble molecules are members of gene families, such as the ephrins, netrins, slits, semaphorins, and laminins. Families of membrane-bound receptors on the

growth cones include adhesion molecules, Eph kinases, neuropilins, plexins, robos, and integrins. Mutations in genes that encode these ligands and receptors can result in developmental neurological disorders.

Glial Cells Promote Synapse Formation

Some Synapses Are Eliminated After Birth An Overall View

o far we have examined three stages in the development of the mammalian nervous system: the formation and patterning of the neural tube, the birth and differentiation of neurons and glial cells, and the growth and guidance of axons. One additional

step must occur before the brain becomes functional: the formation of synapses. Only when synapses are formed and functional can the brain go about the business of processing information.

Three key processes drive synapse formation. First, axons make choices among many potential postsynaptic partners. By forming synaptic connections only on particular target cells, neurons assemble functional circuits that can process information. Usually synapses must be formed at specific sites on the postsynaptic cell; some axons form synapses on dendrites, others on cell bodies, and yet others on axons or nerve terminals. Cellular and subcellular specificity are evident throughout the brain, but we will illustrate the general features of synapse formation with a few well-studied classes of neurons.

Second, after cell-cell contacts have formed, the portion of the axon that contacts the target cell differentiates into a presynaptic nerve terminal, and the domain of the target cell contacted by the axon differentiates into a specialized postsynaptic apparatus. Precise coordination of pre- and postsynaptic differentiation depends on interactions between the axon and its target cell. Much of what we know about these interactions comes from studies of the neuromuscular junction, the synapse between motor neurons and skeletal muscle fibers. The simplicity of this synapse made it a favorable system to probe the structural and electrophysiological principles of chemical synapses, and this simplicity has also helped in the analysis of developing synapses. In this chapter we use the neuromuscular synapse to illustrate key features of synaptic development, and we also apply insights from this peripheral synapse to examine the synapses that form in the central nervous system.

Finally, once formed, synapses continue to mature, often undergoing major rearrangements. One striking aspect of later development is the wholesale elimination of a large fraction of synapses, a process that is usually accompanied by the growth and strengthening of surviving synapses. Like neuronal cell death (see Chapter 53), synapse elimination is a puzzling and seemingly wasteful step in neural development. It is increasingly clear, however, that it plays a key role in refining initial patterns of connectivity. We will discuss the main features of synapse elimination at the neuromuscular junction, where it has been studied intensively, as well as at synapses between neurons, where it also is prominent.

Throughout this chapter we emphasize the interplay of molecular programs and neural activity in shaping synaptic patterns. Synapse formation stands at an interesting crossroads in the sequence of events that assemble the nervous system. The initial steps in this process appear to be "hardwired" by molecular programs. However, as soon as synapses form, the nervous system begins to function, and the activity of neural circuits plays a critical role in subsequent development. Indeed, the information-processing capacity of the nervous system is refined through its use, most dramatically in early postnatal life but also into adulthood. In this sense the nervous system continues to develop throughout life. This discussion will be a useful prelude to Chapter 56, where we discuss how genes and the environment—nature and nurture—interact to customize nervous systems early in postnatal life.

Recognition of Synaptic Targets Is Specific

Once axons reach their designated target areas they must choose appropriate synaptic partners from the many potential targets within easy reach. Although synapse formation is thought to be a selective process at both cellular and subcellular levels, few of the molecules that confer synaptic specificity have been identified.

Recognition Molecules Promote Selective Synapse Formation

The specificity of synaptic connections is particularly evident when intertwined axons select subsets of target cells. In these cases axon guidance and selective synapse formation can be distinguished. The first report of such specificity came more than 100 years ago when J. N. Langley, studying the autonomic nervous system, proposed the first version of a chemospecificity hypothesis (see Chapter 54).

Langley observed that autonomic preganglionic neurons are generated at distinct rostrocaudal levels of the spinal cord. Their axons enter sympathetic ganglia together but form synapses with different postsynaptic neurons that innervate distinct targets. Using behavioral assays as a guide, Langley inferred that the axons of preganglionic neurons located in the rostral spinal cord form synapses on ganglion neurons that project their axons to relatively rostral targets such as the eye, whereas neurons that derive from more caudal regions of the spinal cord synapse on ganglion neurons that project to caudal targets such as the ear (Figure 55–1A). He then showed that similar patterns were reestablished after the preganglionic axons were severed and allowed to regenerate, leading him to postulate that some sort of molecular recognition was responsible (Figure 55–1B, C).

Electrophysiological studies later confirmed Langley's intuition about the specificity of synaptic connections in these ganglia. Moreover, this selectivity is apparent from early stages of innervation, even though specific types of postsynaptic neurons are interspersed within the ganglion. The reestablishment of selectivity in adults after nerve damage shows that specificity does not emerge through peculiarities of embryonic timing or neuronal positioning.

To illustrate the idea of target specificity in more detail we will consider the axons of developing retinal ganglion cells. These neurons differ in their response properties—some ganglion neurons respond to increases in light level (ON cells), others to decreases (OFF cells), others to moving objects, and still others to light of a particular color. The axons of all ganglion cells run through the optic nerve, forming parallel axonal pathways from the retina to the brain.

The response properties of each class of ganglion neurons depend on the synaptic inputs they receive from amacrine and bipolar interneurons, which in turn receive synapses from light-sensitive photoreceptors. All of the synapses from bipolar and amacrine cells onto ganglion cell dendrites occur in a narrow zone of the retina called the inner plexiform layer (see Chapter 26). Axons and dendrites therefore have the daunting task of recognizing their correct partners within a large crowd of inappropriate bystanders.

In the inner plexiform layer the processes of different amacrine and bipolar cell types, as well as the dendrites of functionally distinct ganglion cell types, branch and synapse in different sublayers. The dendrites of ON and OFF cells are restricted to inner and outer portions of the plexiform layer, respectively, and therefore receive synapses from different interneurons (Figure 55–2). There are a dozen sublayers within the

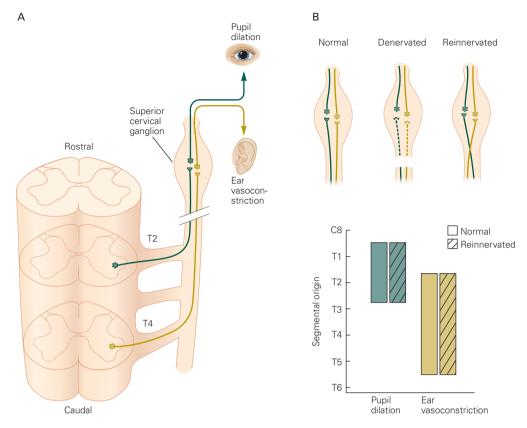

Figure 55–1 Preganglionic motor neurons regenerate selective connections with their sympathetic neuronal targets.

A. Preganglionic motor neurons arise from different levels of the thoracic spinal cord. Axons that arise from rostrally located thoracic neurons innervate superior cervical ganglion neurons that project to rostral targets, including the eye muscles. Axons that arise from neurons at caudal levels of the thoracic spinal cord innervate ganglion neurons that project to more caudal targets, such as the blood vessels of the ear.

These two classes of ganglion neurons are intermingled in the ganglion, which suggested to J. N. Langley that preganglionic axons from different thoracic levels selectively form synapses with neurons that terminate in specific peripheral targets.

B. After nerve damage in adults, similar segment-specific patterns of connectivity are established through reinnervation, supporting the notion that synapse formation is selective. (Reproduced, with permission, from Nja and Purves 1977.)

inner plexiform layer, each with its own cohort of synapses. Similar lamina-specific connections are found in many other regions of the brain and spinal cord. For example, in the cerebral cortex distinct populations of axons confine their dendritic arbors and synapses to just one or two of the six main layers.

One clue to the establishment of lamina-specific synapses in the retina comes from the finding that subsets of ganglion neurons in the chick embryo express different classes of immunoglobulin-like adhesion molecules (see Chapter 54). These proteins promote homophilic interactions, that is, they bind to the same protein on other cell surfaces. Moreover, the amacrine and bipolar cells that contact a particular ganglion cell type in a specific sublamina often express the same

adhesion molecules as their target cell (Figure 55–2B). When the characteristic adhesion molecule of a chick retinal ganglion neuron is removed, the cell's dendrites are no longer confined to a specific lamina. Conversely, the dendrites shift to a new lamina when they are forced to express a new immunoglobulin adhesion molecule. Thus a "like-binds-like" recognition system appears to contribute to this instance of synaptic specificity.

A different type of specificity is evident in the olfactory system. In the olfactory epithelium each neuron expresses just one of approximately 1,000 types of receptors. Neurons expressing one receptor are randomly distributed across a large sector of the epithelium, yet all of their axons converge on the dendrites of just a few target neurons in the olfactory bulb,

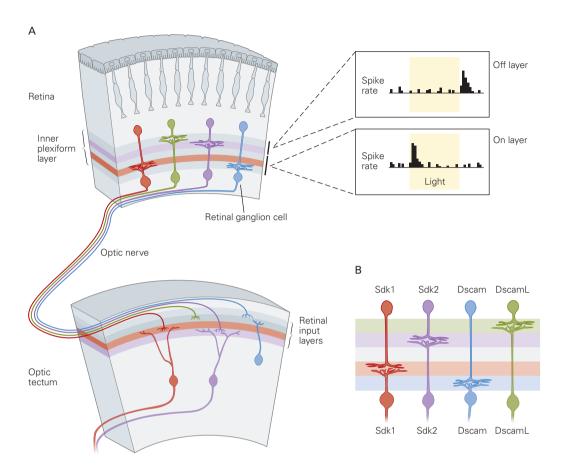

Figure 55–2 Retinal ganglion neurons form layer-specific synapses. (Reproduced, with permission, from Sanes and Yamagata 2009.)

A. The dendrites of retinal ganglion neurons receive input from the processes of retinal interneurons (amacrine and bipolar cells) in the inner plexiform layer, which is subdivided into at least 10 sublaminae. Specific subsets of interneurons and ganglion cells often arborize and synapse in just one layer. These lamina-specific connections determine which aspects of visual stimuli (their onset or offset) activate each type of retinal

ganglion cell. The responses of OFF and ON retinal ganglion cells are shown on the right.

B. Immunoglobulin superfamily adhesion molecules (Sdk1, Sdk2, Dscam, and DscamL) are expressed by different subsets of amacrine and retinal ganglion neurons in the developing chick embryo. Amacrine neurons that express one of these four proteins form synapses with retinal ganglion cells that express the same protein. Manipulating Sdk or Dscam expression alters these patterns of lamina-specific arborization.

forming synapse-rich glomeruli (Figure 55–3A). When an individual olfactory receptor is deleted, the axons that normally express the receptor reach the olfactory bulb but fail to converge into specific glomeruli or to terminate on the appropriate postsynaptic cells (Figure 55–3B). Conversely, when neurons are forced to express a different odorant receptor, their axons form glomeruli at a different position within the olfactory bulb (Figure 55–3C).

Together these experiments suggest that olfactory receptors not only determine a neuron's responsiveness to specific odorants but also help the axon to form appropriate synapses on target neurons. Specific

olfactory receptors may serve as recognition molecules, but it seems more likely that they influence the expression and activity of other receptor systems that contribute to the guidance of olfactory axons. In support of this view, recognition molecules have been found to regulate the interactions of olfactory axons with each other and with their targets.

Different Synaptic Inputs Are Directed to Discrete Domains of the Postsynaptic Cell

Nerve terminals not only discriminate among candidate targets, they also terminate on a specific portion

of the target neuron. In many areas of the brain axons arriving in layered structures often confine their terminals to one layer, even if the dendritic tree of the postsynaptic cell traverses numerous layers. In the cerebellum the axons of different types of neurons terminate on distinct domains of the Purkinje neurons. Granule cell axons contact distal dendritic spines, climbing fiber axons contact proximal dendritic shafts, and basket cell axons contact the axon hillock and initial segment (Figure 55–4).

Such specificity presumably relies on molecular cues on the postsynaptic cell surface. For Purkinje neurons of the cerebellum one such cue is neurofascin, an adhesion molecule of the immunoglobulin superfamily. Neurofascin is present at high levels on the axonal initial segment and directs basket cells to form axons selectively on this axonal domain. Adhesion molecules can therefore also serve as recognition molecules for particular domains of a neuron. Since individual neurons can form synapses with several classes of pre- and postsynaptic cells, it follows that each neuronal subtype must express a variety of synaptic recognition molecules.

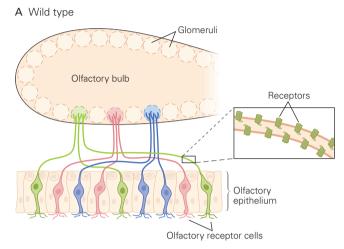

Neural Activity Sharpens Synaptic Specificity

So far we have emphasized the role of recognition molecules in the formation of synapses. Once synapses form, neural activity within the circuit plays a critical role in refining synaptic patterns. In the retinotectal system interactions between ephrins and Eph kinases result in formation of a crude retinotopic map in the tectum (see Chapter 54).

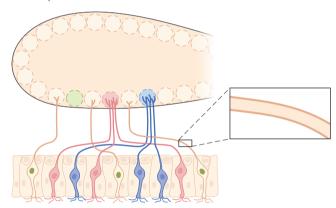

Figure 55–3 Olfactory receptors influence the targeting of sensory axons to discrete glomeruli in the olfactory bulb. (Adapted, with permission, from Sanes and Yamagata 2009.)

A. Each olfactory receptor neuron expresses one of approximately 1,000 possible odorant receptors. Neurons expressing the same receptor are distributed sparsely throughout the olfactory epithelium of the nose. The axons of these neurons form synapses with target neurons in a single glomerulus in the olfactory bulb.

- B. In mouse mutants in which an odorant receptor gene has been deleted, the olfactory neurons that would have expressed the gene send their axons to other glomeruli, in part because these neurons now express other receptors.
- C. When one odorant receptor gene replaces another in a set of olfactory sensory neurons, their axons project to a new glomerulus. Odorant receptor expression may set the overall activity level of the neuron, thus influencing the nature and level of expression of axonal guidance and recognition molecules.)

B Receptor deletion

C Receptor swap

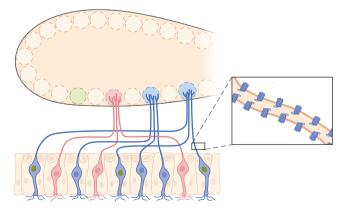

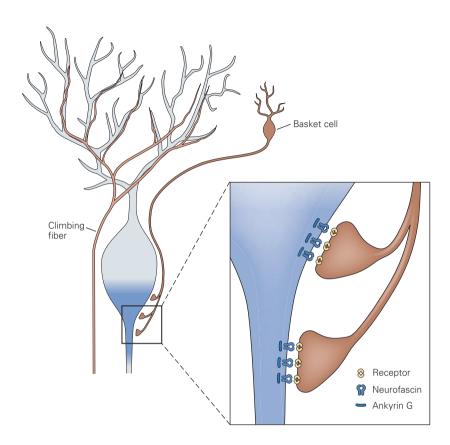

Figure 55-4 The axons of inhibitory interneurons in the cerebellum terminate on a distinct region of the cerebellar Purkinje cell. Many neurons form synapses on cerebellar Purkinje neurons, each selecting a distinct domain on the Purkinje cell. The axons of inhibitory basket cells form most of their synapses on the axon hillock and initial segment. Basket cells select these domains by recognizing neurofascin, a cell surface immunoglobulin superfamily adhesion molecule that is anchored to the initial segment of the axon by ankyrin G. When the localization of neurofascin is perturbed, basket cell axons fail to restrict synapse formation to the initial segment, (Adapted, with permission, from Huang 2006.)

But activity-dependent processes refine the axonal arbors of retinal ganglion cells, thus sharpening the tectal map (Figure 55–5). The axons of retinal ganglion neurons initially form broad diffuse arbors, which gradually become denser but more focused. This refinement is inhibited when the activity of synapses is blocked. Likewise, dendritic arbors of some retinal ganglion cells initially span multiple sublaminae in the inner plexiform layer, then become restricted to narrow ones. The molecular mechanisms of this activity-dependent refinement are largely unknown. One idea is that the level and pattern of neuronal activity regulates the expression of recognition molecules.

These examples illustrate a widespread phenomenon: Molecular cues control initial specificity but, once the circuit begins to function, specificity is sharpened through neural activity. In the two cases mentioned here, sharpening involves loss of synapses. We will return to the process of synapse elimination at the end of this chapter, and consider its consequences for behavior in the next chapter.

In a few cases neural activity can turn an inappropriate target into an appropriate one. This mechanism has been most clearly demonstrated in skeletal muscle, where mammalian muscle fibers can be divided into several categories according to their contractile characteristics. Muscle fibers of particular types express genes for distinctive isoforms of the main contractile proteins, such as myosins and troponins.

Few muscles are composed exclusively of a single type of fiber; most have fibers of all types. Yet the branches of an individual motor axon innervate muscle fibers of a single type, even in "mixed" muscles in which fibers of different types are intermingled (Figure 55–6A). This pattern, sometimes termed motor unit homogeneity, implies a remarkable degree of synaptic specificity. However, matching does not come about solely through recognition in the motor axon of the appropriate type of muscle fiber. The motor axon can also convert the target muscle fiber to an appropriate type. When a muscle is deinnervated at birth, before the properties of its fibers are fixed, a nerve that normally innervates a slow muscle can be redirected to reinnervate a muscle destined to become fast, and vice versa. Under these conditions the contractile properties of the muscle are partially transformed in a direction imposed by the firing properties of the motor nerve (Figure 55–6B, C).

Different patterns of neural activity are responsible for the switch in muscle properties. Most strikingly, direct electrical stimulation of a muscle with patterns normally evoked by slow or fast nerves leads to changes that are nearly as dramatic as those produced by cross-innervation (Figure 55–6D). Although activity-based conversion of the type used at the neuromuscular junction is unlikely to be a major contributor to synaptic specificity in the central nervous system, it raises the possibility that central axons can modify the properties of their synaptic targets, contributing to the diversification of neuronal subtypes and refining connectivity imposed by recognition molecules.

Principles of Synaptic Differentiation Are Revealed at the Neuromuscular Junction

The neuromuscular junction comprises three types of cells: a motor neuron, a muscle fiber, and Schwann cells. All three types are highly differentiated in the region of the synapse.

The process of synapse formation is initiated when a motor axon, guided by the multiple factors described in Chapter 54, reaches a developing skeletal muscle and approaches an immature muscle fiber. Contact is made and the process of synaptic differentiation begins. As the growth cone begins its transformation into a nerve terminal, the portion of the muscle surface opposite the nerve terminal begins to acquire its own specializations. As development proceeds, synaptic components are added and structural signs of synaptic differentiation become apparent in the pre- and post-synaptic cells and in the synaptic cleft. Eventually the neuromuscular junction acquires its mature and complex form (Figure 55–7A, B).

Three general features of neuromuscular junction development have provided clues about the molecular mechanisms that underlie synapse formation. First, nerve and muscle organize each other's differentiation. In principle, the precise apposition of preand postsynaptic specializations might be explained by independent programming of nerve and muscle properties. However, in muscle cells cultured alone

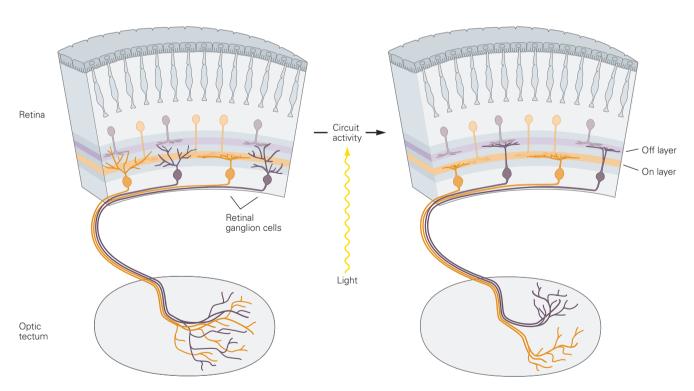

Figure 55–5 Electrical activity refines the specificity of synaptic connections in the retina. Some retinal ganglion cells initially form dendritic arbors that are limited to specific sublaminae in the inner plexiform layer of the retina, whereas others initially form diffuse arbors that are later pruned to form large specific patterns. Similarly, the axonal arbors of retinal

ganglion cells initially innervate a large region of their target fields in the lateral geniculate nucleus and optic tectum. This expansive axonal arbor is then refined so as to concentrate many branches in a small region. Abolishing electrical activity in retinal ganglion cells decreases the remodeling of dendritic and axonal arbors.

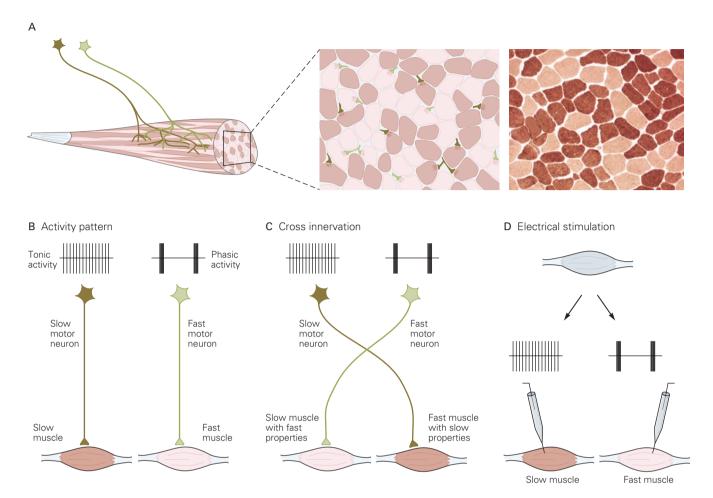

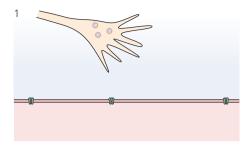

Figure 55–6 The pattern of motor neuron activity can change the biochemical and functional properties of skeletal muscle cells

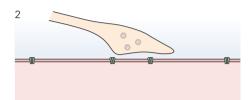

- A. Muscle fibers have characteristic metabolic, molecular, and electrical properties that identify them as "slow" (tonic) or "fast" (phasic) types. The micrograph on the right shows a section of muscle tissue with histochemical staining for myosin ATPase. The middle sketch shows a section through the muscle, in which motor neurons (green and brown) form synapses on a single type of muscle fiber. (Photo reproduced, with permission, from Arthur P. Hays.)
- **B.** Motor neurons that connect with fast and slow muscle fibers (fast and slow motor neurons) exhibit distinct patterns of electrical activity: steady low frequency (tonic) for slow and intermittent high-frequency bursts (phasic) for fast.
- C. Cross-innervation experiments showed that some property of the motor neuron helps to determine whether muscle fibers are fast or slow. Cross-innervation was achieved by surgically rerouting fast axons to slow muscle and vice versa. Although the properties of the motor neurons are little changed, the properties of the muscle change profoundly. For example, fast motor neurons induce fast properties in the slow muscle. (Adapted, with permission, from Salmons and Sreter 1976.)
- **D.** The effects of innervation by fast and slow nerves on muscle are mediated in part by their distinct patterns of activity. When a fast muscle is stimulated in a slow tonic pattern, the muscle acquires slow electrical and molecular properties. Conversely, fast phasic stimulation of a once slow muscle can convert it to a faster type.

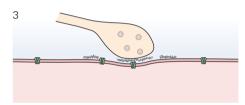

acetylcholine (ACh) receptors are generally distributed uniformly on the surface, although some are clustered as in mature postsynaptic membranes. Yet when motor neurons are added to the cultures they extend neurites that contact the muscle cells more or less randomly, instead of seeking out the ACh receptor

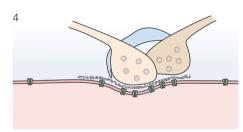

clusters. New receptor clusters appear precisely at the points of contact with the presynaptic neurites while preexisting uninnervated clusters eventually disperse (Figure 55–8). Thus factors on or released by motor axons exert a profound influence on the synaptic organization of the muscle cell. Likewise, muscles signal

A Development stages

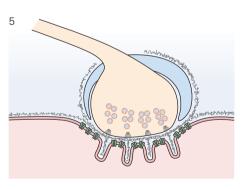

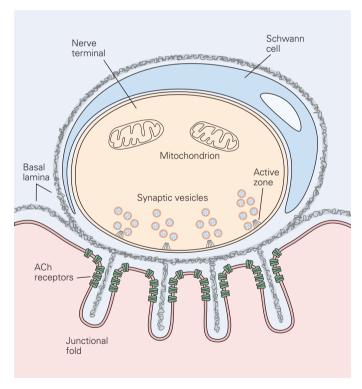

Figure 55–7 The neuromuscular junction develops in sequential stages.

A. A growth cone approaches a newly fused myotube (1) and forms a morphologically unspecialized but functional contact (2). The nerve terminal accumulates synaptic vesicles and a basal lamina forms in the synaptic cleft (3). As the muscle matures, multiple axons converge on a single site (4). Finally, all axons but one are eliminated and the surviving terminal matures (5). (Adapted, with permission, from Hall and Sanes 1993.)

B Mature neuromuscular junction

B. At the mature neuromuscular junction, pre- and postsynaptic membranes are separated by a synaptic cleft that contains basal lamina and extracellular matrix proteins. Vesicles are clustered at presynaptic release sites, transmitter receptors are clustered in the postsynaptic membrane, and nerve terminals are coated by Schwann cell processes. (Image reproduced, with permission, courtesy of T. Gillingwater.)

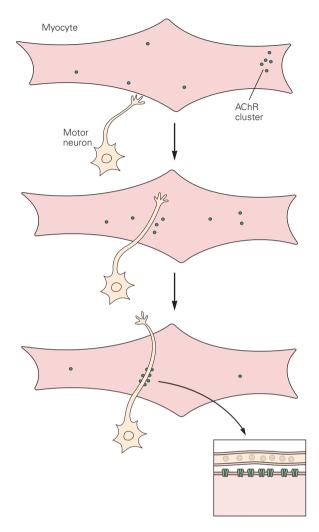

Figure 55–8 Nerve and muscle cells express synaptic components, but synaptic organization requires cell interactions. Acetylcholine receptors (AChR) are synthesized by muscle cells cultured without neurons. Many receptors are diffusely distributed, but some form high-density aggregates similar to those found in the postsynaptic membrane of the neuromuscular junction. When neurons first contact muscle they do not restrict themselves to the receptor-rich aggregates. Instead, new receptor aggregates form at sites of neuritemuscle contact, and many of the preexisting clusters disperse. Similarly, motor axons contain synaptic vesicles that cluster at sites of neurite contact with muscle cells. (Adapted, with permission, from Anderson and Cohen 1977; Lupa, Gordon, and Hall 1990.)

retrogradely to motor nerve terminals. When motor neurons in culture extend neurites, they assemble and transport synaptic vesicles, some of which form aggregates similar to those found in nerve terminals. When the neurites contact muscle cells, new vesicle clusters form opposite the muscle membrane, and most of the preexisting clusters disperse.

Second, as these studies showed, motor neurons and muscle cells can synthesize and arrange most synaptic components without each other's help. Uninnervated myotubes can synthesize functional ACh receptors and gather them into high-density aggregates. Likewise, motor axons can form synaptic vesicles and cluster them into varicosities in the absence of muscle. In fact, vesicles in growth cones can synthesize and release ACh in response to electrical stimulation, before the growth cone has reached its target cells. Thus the developmental signals that pass between nerve and muscle do not induce wholesale changes in cell properties; rather they assure that components of the pre- and postsynaptic machinery are organized at the correct time and in the right places. It is useful therefore to think of the intercellular signals that control synaptogenesis as organizers rather than inducers.

A third key feature of neuromuscular junction development is that new synaptic components are added in several distinct steps. The newly formed synapse is not simply a prototype of a fully developed synapse. Although nerve and muscle membrane form close contacts at early stages of synaptogenesis, only later does the synaptic cleft widen and the basal lamina appear. Similarly, ACh receptors accumulate in the postsynaptic membrane before acetylcholinesterase accumulates in the synaptic cleft, and the postsynaptic membrane acquires junctional folds only after the nerve terminal has matured. Several different axons innervate each myotube around the time of birth, but during early postnatal life all but one axon withdraws.

This elaborate sequence is unlikely to be orchestrated by the simple act of contact between nerve and muscle. More probably, multiple signals pass between the cells—the nerve sends a signal to the muscle that triggers the first steps in postsynaptic differentiation, at which point the muscle sends a signal that triggers the initial steps of nerve terminal differentiation. The nerve then sends further signals to the muscle, and this interaction continues.

We now consider retrograde (from muscle to nerve) and anterograde (from nerve to muscle) organizers in more detail.

Differentiation of Motor Nerve Terminals Is Organized by Muscle Fibers

Soon after the growth cone of a motor axon contacts a developing myotube, a rudimentary form of neuro-transmission begins. The axon releases ACh in vesicular packets, the transmitter binds to receptors, and the muscle responds with depolarization and weak contraction

The onset of transmission at the new synapse reflects the intrinsic capabilities of each synaptic partner. Nevertheless, these intrinsic capabilities cannot readily explain the marked increase in the rate of transmitter release that occurs after nerve-muscle contact is made, nor can they explain the accumulation of synaptic vesicles and the assembly of active zones in the small portion of the motor axon that contacts the muscle surface. These developmental steps require signals from muscle to nerve.

A clue to the source of these signals came from studies on the reinnervation of adult muscle. Although axotomy leaves muscle fibers denervated and leads to insertion of ACh receptors in nonsynaptic regions, the postsynaptic apparatus remains largely intact. It is still recognizable by its synaptic nuclei, junctional folds, and the ACh receptors, which remain far more densely packed in synaptic areas than in extrasynaptic areas of the cell. Damaged peripheral axons regenerate readily (unlike those in the central nervous system) and form new neuromuscular junctions that look and perform much like the original ones.

A century ago, Fernando Tello y Muñóz, a student of Santiago Ramón y Cajal, noted that the new junctions form at preexisting synaptic sites on the denervated muscle fibers even though the postsynaptic specializations occupy only 0.1% of the muscle fiber surface (Figure 55–9A). Later, electron microscopy showed that specialization in the axon occurs only in the terminals that contact the muscle. For example, active zones form directly opposite the mouths of the postsynaptic junctional folds. These findings imply that motor axons recognize signals associated with the postsynaptic apparatus.

When regenerating axons reach a muscle fiber they encounter the basal lamina of the synaptic cleft. To explore the significance of this association, muscles were damaged in vivo in a way that killed the muscle fibers but left their basal lamina intact. The necrotic fibers were phagocytized, leaving behind basal lamina sheaths on which synaptic sites were readily recognizable. At the same time that the muscle was damaged the nerve was cut and allowed to regenerate. Under these conditions motor axons reinnervated the empty basal lamina sheaths, contacting synaptic sites as precisely as they would have if muscle fibers were present. Moreover, nerve terminals developed at these sites and active zones even formed opposite struts of basal lamina that once lined junctional folds. These observations implied that components of the basal lamina organize presynaptic specialization (Figure 55–9B).

Several such molecular organizers have now been identified. Among the best studied are isoforms of the

protein laminin. Laminins are major components of all basal laminae and promote axon outgrowth in many neuronal types (see Chapter 54). They are heterotrimers of α , β , and γ chains, comprising a family of at least five α , four β , and three γ chains. Muscle fibers synthesize multiple laminin isoforms and incorporate them into the basal lamina. Laminin-211, a heterotrimer containing the α 2, β 1, and γ 1 chains, is the major laminin in the basal lamina, and its absence leads to severe muscular dystrophy. In the synaptic cleft, however, isoforms bearing the β 2 chain predominate (Figure 55–10A).

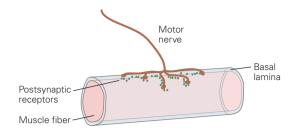

In vitro motor axons that encounter a deposit of $\beta 2\text{-containing}$ laminin stop growing, accumulate synaptic vesicles, and acquire the ability to release neurotransmitter. Conversely, the development of nerve terminals and Schwann cells is perturbed in mutant mice that lack the $\beta 2$ laminin (Figure 55–10B). These laminins appear to act by binding to voltage-sensitive calcium channels that reside in the axon terminal membrane, where they couple activity to transmitter release. Laminins act on the extracellular domain of the channels whereas the intracellular segment recruits or stabilizes other components of the release apparatus.

Because presynaptic specialization proceeds to some extent in the absence of laminins, additional retrograde organizers of axonal specialization must exist. Among these are members of the fibroblast growth factor and collagen IV families, both produced by muscle cells. Thus target-derived proteins from multiple families collaborate to organize the presynaptic nerve terminal.

Differentiation of the Postsynaptic Muscle Membrane Is Organized by the Motor Nerve

Soon after myoblasts fuse to form myotubes, the genes that encode ACh receptor subunits are activated. Receptor subunits are synthesized, assembled into pentamers in the endoplasmic reticulum, and inserted into the plasma membrane. As noted above, some receptors spontaneously form aggregates, but the majority are distributed throughout the membrane at a low density, approximately 1,000 per μ m².

Once synapse formation is complete, however, the distribution of the receptors changes drastically. The receptors become concentrated at the synaptic sites of the membrane (to a density up to 10,000 per μm^2) and depleted in the nonsynaptic membrane (reduced to 10 per μm^2 or less). This thousand-fold difference in ACh receptor density occurs a few tens of micrometers from the edge of the nerve terminal.

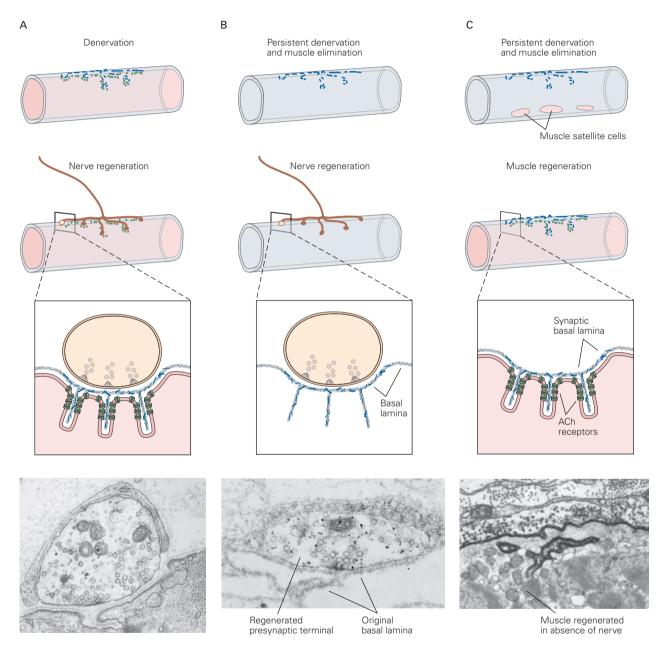

Figure 55–9 Synaptic portions of basal lamina contain proteins that organize developing nerve terminals.

A. After nerve damage motor axons regenerate and form new neuromuscular junctions. Nearly all of the new synapses form at the original synaptic sites. (Micrograph reproduced, with permission, from Glicksman and Sanes 1983.)

B. A strong preference for innervation at original synaptic sites persists even after the muscle fibers have been removed, leaving behind basal lamina "ghosts." Regenerated axons develop synaptic specialization on contact with the original synaptic

sites on the basal lamina. (Micrograph reproduced, with permission, from Glicksman and Sanes 1983.)

C. Following denervation of a skeletal muscle fiber and elimination of mature muscle fibers, muscle satellite cells proliferate and differentiate to form new myofibers. The expression of ACh receptors on the regenerated myofiber surface is concentrated in the synaptic areas of basal lamina, even when reinnervation is prevented. (Micrograph reproduced, with permission, from Burden, Sargent, and McMahan 1979.)

A Wild type B Laminin mutant Schwann cell invasion of synaptic cleft Schwann cell invasion of synaptic cleft Schwann cell invasion of synaptic cleft Muscle

Figure 55–10 Different laminin isoforms are localized at synaptic and extrasynaptic areas of the basal lamina.

A. Different laminin isoforms are found in synaptic (brown) and extrasynaptic (green) areas of basal lamina. Isoforms, containing the $\beta 2$ chain, are concentrated in the synaptic areas.

B. Maturation of neuromuscular junctions is impaired in mice lacking $\beta 2$ laminins. These mutants have few active zones, and the synaptic cleft is invaded by Schwann cell processes (blue). (Micrograph reproduced, with permission, from Noakes et al. 1995.)

Appreciation of the critical role of the nerve in the redistribution of ACh receptors inspired a search for factors that might promote their clustering. This quest led to the discovery of a proteoglycan, agrin. Agrin is synthesized by motor neurons, transported down the axon, released from nerve terminals, and incorporated into the synaptic cleft (Figure 55–11A, B). Some agrin isoforms are also made by muscle cells, but the neuronal isoforms are about a thousand-fold more active in aggregating ACh receptors.

The phenotype of mutant mice lacking agrin shows that agrin has a central role in the organization of ACh receptors. Agrin mutants have grossly perturbed neuromuscular junctions and die at birth. The number, size, and density of ACh receptor aggregates are severely reduced in these mice (Figure 55–11C). Other components of the postsynaptic apparatus—including cytoskeletal, membrane, and basal lamina proteins—are also reduced. Interestingly, the differentiation of presynaptic elements is also perturbed. However, the defects in the presynaptic element do not result directly from lack of agrin in the motor neuron, but rather indirectly from the failure of the disorganized postsynaptic apparatus to generate signals for presynaptic specialization.

How does agrin work? Agrin's major receptor is a complex of a muscle-specific tyrosine kinase called MuSK (muscle-specific trk-related receptor with a kringle domain) and a coreceptor subunit called LRP4 (Figure 55–11A). MuSK is normally concentrated at synaptic sites in the muscle membrane, and muscles of mutant mice lacking MuSK do not have ACh

receptor clusters (Figure 55–11C). Myotubes generated in vitro from these mutants express normal levels of ACh receptors, but these receptors cannot be clustered by agrin. MuSK therefore appears to be a critical component of the receptor for agrin. LRP4 functions together with MuSK, an adaptor protein Dok-7, and a cytoplasmic protein rapsyn. LRP4 forms a complex with MuSK and binds agrin efficiently. Dok-7 binds MuSK and signals to rapsyn, which is also necessary for ACh receptor clustering. Rapsyn is co-localized with ACh receptors in vivo, is present at ACh receptor clusters soon after they form, and can induce the aggregation of ACh receptors in vitro. In mice lacking rapsyn muscles form normally and ACh receptors accumulate in normal numbers but fail to aggregate at the synaptic sites on the membrane.

Thus an extracellular protein (agrin), transmembrane proteins (MuSK and LRP4), an adaptor protein (Dok-7), and a cytoskeletal protein (rapsyn) form a chain that links commands from the motor axon to ACh receptor clustering in the muscle membrane.

Nevertheless, postsynaptic differentiation can occur in the absence of this transduction pathway. This capacity was apparent in early studies on cultured muscle (see Figure 55–8) and is also seen in vivo: ACh receptor clusters form initially but then disperse in agrin mutants (Figure 55–11C). Clustering also occurs in muscles that lack innervation entirely. Conversely, no clustering occurs in mutant animals lacking MuSK, LRP4, Dok-7, or rapsyn. Thus the signaling pathway that initiates postsynaptic differentiation can be activated without agrin, but agrin is required to maintain clustering of ACh receptors.

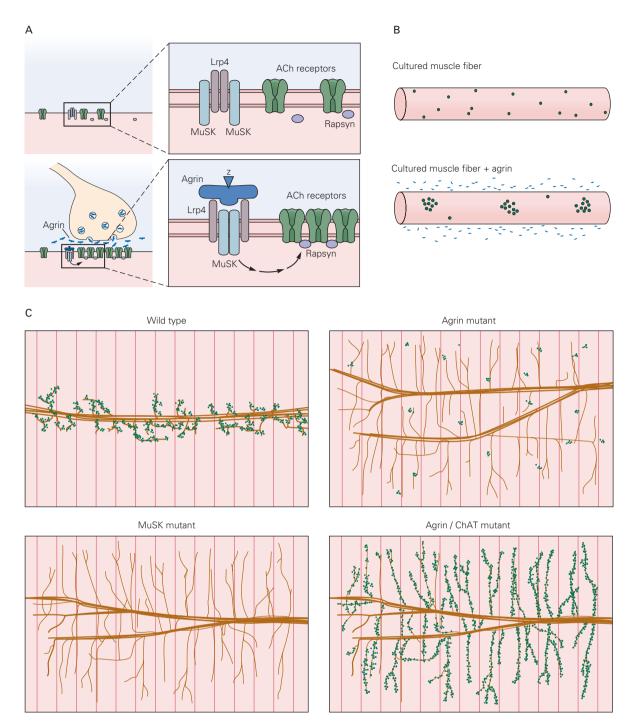

Figure 55–11 Agrin induces aggregation of ACh receptors at synaptic sites.

A. Agrin is a large (~400 kDa) extracellular matrix proteogly-can. Alternative splicing includes a "z" exon that confers the ability to cluster ACh receptors. When released by a nerve terminal, agrin binds Lrp4 on the muscle membrane, activating the membrane-associated receptor tyrosine kinase MuSK and triggering an intracellular cascade that results in ACh receptor clustering. Clustering is mediated by rapsyn, a cytoplasmic ACh receptor-associated protein. (Adapted, with permission, from DeChiara et al. 1996.)

B. Few ACh receptor clusters form on myofibers grown in culture under control conditions, but addition of agrin induces ACh receptor clustering. (Adapted, with permission, from Misgeld et al. 2005.)

C. Muscles from wild type neonatal mice and from three mutant types. Muscles were labeled for ACh receptors (green) and motor axons (brown). In wild type mice ACh receptor clusters have formed under each nerve terminal by birth, whereas in agrin mutants most clusters have dispersed. ACh receptors are also absent in MuSK mutant mice. When the genes for agrin and ChAT (choline acetyltransferase) are mutated, clusters of ACh receptors remain, indicating that agrin works by counteracting receptor dispersion mediated by ACh. All three mutant conditions also show axonal abnormalities, reflecting the inability of the muscle to supply retrograde factors. (ACh, acetylcholine; MuSK, muscle-specific trk-related receptor with a kringle domain.) (Adapted, with permission, from Gautam et al. 1996.)

The role of agrin is perhaps best understood in terms of the requirement that pre- and postsynaptic specializations be perfectly aligned. Acetycholine receptor aggregates persist in uninnervated muscles but disappear in agrin mutant muscles, suggesting that axons sculpt the postsynaptic membrane through the combined action of agrin and a dispersal factor. One major dispersal factor is ACh itself; clustering persists in mutants that lack both agrin and ACh (Figure 55–11C). Thus agrin may render ACh receptors immune to the declustering effects of ACh. Through a combination of positive and negative factors, the motor neuron ensures that the patches of postsynaptic membrane contacted by axon branches are rich in ACh receptors.

The Nerve Regulates Transcription of Acetylcholine Receptor Genes

Along with redistribution of ACh receptor in the plane of the membrane, the motor nerve orchestrates the transcriptional program responsible for expression of ACh receptor genes in muscle. To understand this aspect of transcriptional control, it is important to appreciate the geometry of the muscle.

Individual muscle fibers are often more than a centimeter long and contain hundreds of nuclei along their length. Most nuclei are far from the synapse, but a few are clustered beneath the synaptic membrane, so that their transcribed and translated products do not have far to go to reach the synapse. In newly formed myotubes most nuclei express genes encoding the ACh receptor α -, β -, δ -, and γ -subunits. In adult muscles, however, only synaptic nuclei express ACh receptor genes; nonsynaptic nuclei do not. This change in pattern occurs in three steps.

During early stages of synapse formation the ACh receptor subunit genes are expressed at higher levels in synaptic nuclei than in their nonsynaptic neighbors (Figure 55–12). Signals acting through MuSK are needed for this specialization. Around the time of birth, ACh receptor gene expression shuts down in nonsynaptic nuclei. This change reflects a repressive effect of the nerve, as originally shown by studies of denervated muscle. When muscle fibers are denervated, as happens when the motor nerve is damaged, the density of ACh receptors in the postsynaptic membrane increases markedly, a phenomenon termed *denervation supersensitivity*.

This repressive effect of the nerve is mediated by electrical activation of the muscle. Under normal conditions the nerve keeps the muscle electrically active, and active muscle synthesizes fewer ACh receptors than inactive muscle. Indeed, direct stimulation of denervated

muscle through implanted electrodes decreases ACh receptor expression, preventing or reversing the effect of denervation (Figure 55–12B). Conversely, when nerve activity is blocked by application of a local anesthetic, the number of ACh receptors throughout the muscle fiber increases, even though the synapse is intact.

In essence, then, the nerve uses ACh to repress expression of ACh receptor genes extrasynaptically. Current that passes through the channel of the receptor leads to an action potential that propagates along the entire muscle fiber. This depolarization opens voltage-dependent Ca²⁺ channels, leading to an influx of Ca²⁺, which activates a signal transduction cascade that reaches nonsynaptic nuclei and regulates transcription of ACh receptor genes. Thus the same voltage changes that produce muscle contraction over a period of milliseconds also regulate transcription of ACh receptor genes over a period of days.

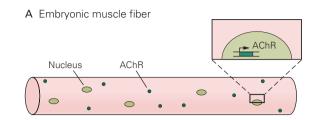

The increase in transcription of ACh receptor genes in nuclei beneath the synapse, along with the decrease in nuclei distant from synapses, leads to localization of ACh receptor mRNA and thus preferential synthesis and insertion of ACh receptors near synaptic sites. This local synthesis is reminiscent of that seen at postsynaptic sites on dendritic spines in the brain. Local synthesis in muscle is advantageous since ACh receptors synthesized near the ends of fibers would never reach the synapse without degradation.

We have used the ACh receptor as an example of postsynaptic differentiation, but many components of the postsynaptic apparatus are regulated in similar ways—their aggregation depends on agrin and MuSK, and their transcription is enhanced in synaptic nuclei and repressed in extrasynaptic nuclei by electrical activity. Thus synaptic components have tailor-made regulatory mechanisms, but many of these components are regulated in parallel.

The Neuromuscular Junction Matures in a Series of Steps

The adult neuromuscular junction is dramatically different in its molecular architecture, shape, size, and functional properties from the simple nerve-muscle contact that initiates neurotransmission in the embryo. Maturation of the nerve terminal, the postsynaptic membrane, and the intervening synaptic cleft occurs in a complex series of steps. We illustrate this step-wise synaptic construction with a continued focus on the development of ACh receptors.

As we have seen, ACh receptors aggregate in the plane of the membrane as the neuromuscular

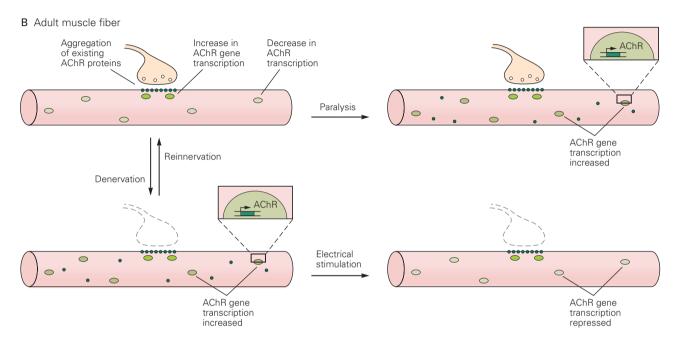

Figure 55–12 Clustering of ACh receptors at the neuromuscular junction results from transcriptional regulation and local protein trafficking.

A. Acetylcholine receptors (AChR) are distributed diffusely on the surface of embryonic myotubes.

B. After the muscle is innervated by a motor axon the number of receptors in extrasynaptic regions decreases, whereas receptor density at the synapse increases. This reflects the aggregation of preexisting receptors and enhanced expression of ACh receptor genes in nuclei that lie directly beneath the

nerve terminal. In addition, the transcription of receptor genes is repressed in nuclei in extrasynaptic regions. Electrical activity in muscle represses ACh gene expression in nonsynaptic nuclei, leading to a lower density of ACh receptors in these regions. The nuclei at synaptic sites are immune to this repressive effect. Following denervation, ACh receptor gene expression is upregulated in extrasynaptic nuclei, although not to the high level attained by synaptic nuclei. Paralysis mimics the effect of denervation, whereas electrical stimulation of denervated muscle mimics the influence of the nerve and decreases the density of ACh receptors in the extrasynaptic membrane.

junction begins to form, and receptor gene transcription is enhanced in synaptic nuclei. A few days later activity begins to decrease the level of extrasynaptic receptors and the stability of receptors changes. In embryonic muscle ACh receptors are turned over rapidly (with a half-life of approximately 1 day) throughout the membrane, whereas in adult muscle they are relatively stable (with a half-life of approximately 2 weeks). The metabolic stabilization of ACh receptors helps concentrate them at synaptic sites and stabilize the postsynaptic apparatus.

During the first few postnatal days the composure of the ACh receptor changes, shuts off the δ gene and activates the ϵ gene. As a result, new ACh receptors inserted in the membrane are composed of α -, β -, δ -, and ϵ -subunits rather than α -, β -, δ -, and γ -subunits. This altered subunit composition tunes the receptor in a way that is suited to its mature function. However, although it occurs at the same time as the metabolic stabilization, the two changes are not causally linked.

These molecular changes in the postsynaptic membrane are accompanied by changes in its shape (Figure 55–13). Soon after birth junctional folds begin to form in the postsynaptic membrane and ACh receptors become concentrated at the crests of the folds, along with rapsyn, whereas other membrane and cytoskeletal proteins are localized in the depths of the folds. The initial aggregate of ACh receptors appears to have a plaque-like appearance. Perforations that undergo fusion and fission eventually transform the dense plaque into a pretzel-shape that follows the branches of the nerve ending. Finally, the postsynaptic membrane enlarges and eventually contains many more ACh receptors than were present in the initial

cluster. Each of these changes occurs while the synapse is functional, implying that ongoing activity plays an important role in synaptic maturation.

Central Synapses Develop in Ways Similar to Neuromuscular Junctions

Synapses in the central nervous system are structurally similar to neuromuscular junctions, and they function in a similar way. Their formation also adheres to the principles of development of the neuromuscular

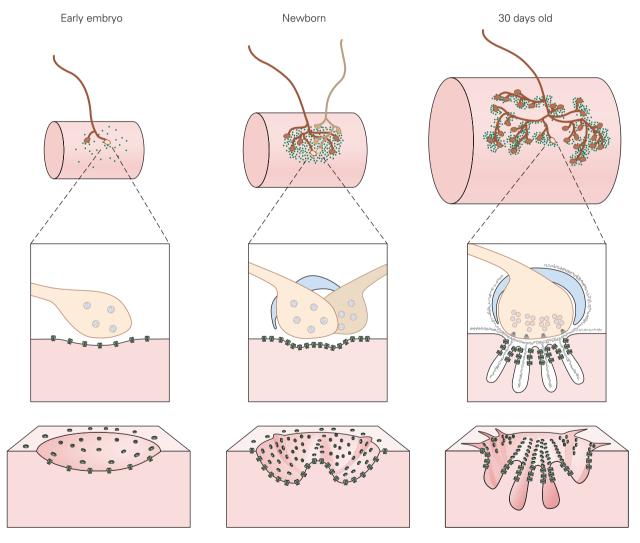

Figure 55–13 The postsynaptic membrane at the neuro-muscular junction matures in stages. During early embryogenesis ACh receptors exist as loose aggregates. Later these aggregates condense into a plaque-like structure. After birth the dense cluster opens up as the nerve develops multiple

terminals. These axon branches expand in an intercalary fashion as the muscle grows, and the plaque indents to form a gutter, which then invaginates to form folds. Receptors are concentrated at the crests of the folds. (Adapted, with permission, from Sanes and Lichtman 2001.)

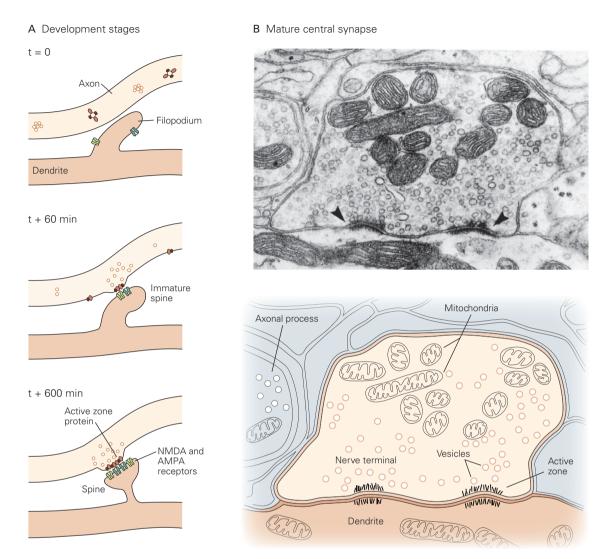

Figure 55–14 Ultrastructure of a synapse in the mammalian central nervous system.

A. Initial contact between an axon and a filopodium on a developing dendrite leads to a stable dendritic spine and an axo-dendritic synapse. This entire process can take as little as 60 minutes.

junction: Pre- and postsynaptic elements regulate each other's differentiation by organizing presynthesized synaptic components rather than by inducing expression of specific genes, and synapses develop in a progressive series of steps (Figure 53–14).

Resolving whether this cellular parallel extends to the molecular level has proven difficult, because of the small size and relative inaccessibility of central synapses. But studies of cultured neurons suggest that the cellular logic of synapse formation is indeed conserved between neuromuscular junctions and central synapses, although different organizers are involved.

Neurotransmitter Receptors Become Localized at Central Synapses

The concentration of neurotransmitter receptors in the postsynaptic membrane is a feature shared by many synapses. In the brain, receptors for glutamate, glycine, GABA (γ -aminobutyric acid), and other neurotransmitters are concentrated in patches of membrane aligned with nerve terminals that contain the corresponding transmitter.

The processes by which these receptors become localized may be similar to those at the neuromuscular

junction. In cultures of dissociated hippocampal neurons, for example, both glutamatergic and GABA-ergic nerve terminals appear to stimulate clustering of appropriate receptors in the postsynaptic membrane (Figure 55–15). The mediators of these effects are unknown. Moreover, nerves can induce expression of genes encoding glutamate receptors in central

Figure 55–15 Localization of neurotransmitter receptors in central neurons. Glutamate and GABA receptors are localized at excitatory and inhibitory synapses in culture. Glutamate receptors are clustered underneath synaptophysin-labeled excitatory nerve terminals, but not all clusters of glutamate receptors are associated with nerve terminals. GABA receptors are clustered under inhibitory terminal boutons that express GAD67. (GABA, γ-aminobutyric acid; GAD, glutamic acid decarboxylase.) (Images reproduced, with permission, from A. M. Craig.)

neurons, much as occurs for ACh receptors in muscle. Finally, electrical activity also regulates expression of neurotransmitter receptors in neurons.

In forming receptor clusters, central neurons face an obvious challenge that myotubes do not: They are contacted by axon terminals from distinct classes of neurons that use different neurotransmitters. Thus the nerve terminal probably has an instructive role in the clustering of receptors. In cultures of hippocampal neurons, glutamatergic and GABAergic axons terminate on adjacent regions of the same dendrite. Initially glutamate and GABA receptors are dispersed, but soon each type becomes selectively clustered beneath terminals that release that neurotransmitter. This observation implies the existence of multiple clustering signals with parallel pathways of signal transduction.

In central neurons several distinct proteins have been found to play a role similar to that of rapsyn at the neuromuscular junction. One, gephyrin, is highly concentrated in the synaptic densities at glycinergic and some GABAergic synapses (Figure 55-16). Gephyrin is not structurally related to rapsyn but appears to have similar functions: it links the receptors to the underlying cytoskeleton. Its overexpression in nonneural cells leads to clustering of glycine receptors. Moreover, in gephyrin-deficient mutant mice glycine receptor clusters fail to form at inhibitory synapses. Similarly, a class of proteins that share conserved segments called PDZ domains—the prototypes being PSD-95 or SAP-90—facilitates clustering of NMDAtype (N-methyl-D-aspartate) glutamate receptors and their associated proteins (Figure 55-16). Still other PDZ-containing proteins interact with AMPA-type (α-amino-3-hydroxy-5-methylisoxazole-4-propionate) and metabotropic glutamate receptors. Different presynaptic signals may activate pathways that lead to the expression and localization of gephyrin, PSD-95, and other functionally related proteins.

Synaptic Organizing Molecules Pattern Central Nerve Terminals

Nerve terminals at neuromuscular junctions and central synapses are quite similar, reflecting the fact that the motor axon is part of a central neuron. Most of the major protein components of synaptic vesicles have now been isolated and appear to be identical at both types of synapses. Likewise, the mechanisms of transmitter release differ only quantitatively, not qualitatively.

However, the synaptic cleft differs dramatically. Whereas muscle fibers are ensheathed by a basal lamina that has a distinctive molecular structure at the neuromuscular junction, central neurons do not have

a prominent basal lamina. Central synaptic clefts contain no detectable laminin or collagen. Instead, intercellular adhesion at central synapses may involve the interaction of matched adhesion molecules on preand postsynaptic membranes, with no intermediate matrix.

Several adhesion molecules link the pre- and postsynaptic membrane and also pattern presynaptic differentiation as synapses form. Among them is a class of proteins in postsynaptic membranes, the neuroligins. Their receptors on axonal membranes are the neurexins. The ability of neuroligins to promote presynaptic differentiation was first revealed by culturing neurons with nonneural cells engineered to express neuroligins. In culture synaptic vesicles form clusters at sites of contact with the neuroligin-expressing cells and they are capable of releasing neurotransmitter when stimulated (Figure 55-17). Conversely, neurotransmitter receptors in dendrites aggregate at sites that contact nonneural cells engineered to express neurexins. Thus neurexin-neuroligin interactions facilitate precise apposition of pre- and postsynaptic specializations. Differences among neurexin and neuroligin protein isoforms may also contribute to the matching of excitatory and inhibitory nerve terminals with excitatory and inhibitory neurotransmitter receptors.

How do neurexins and neuroligins work? Part of the answer is that their carboxy terminal tails bind to PDZ domains in proteins such as PSD-95 (Figure 55–16). Indeed, a remarkable number of proteins in both pre- and postsynaptic membranes have PDZ domainbinding motifs, notably adhesion molecules, neurotransmitter receptors, and ion channels. Moreover, many cytoplasmic proteins that possess PDZ domains are present in nerve terminals and beneath the postsynaptic membrane. Thus PDZ-containing proteins can serve as scaffolding molecules that link key components on both sides of the synapse. Interactions of proteins such as neurexins and neuroligins may provide a means of coupling the intercellular interactions required for synaptic recognition to the intracellular interactions required to cluster synaptic components within the cell membrane.

An indication of their critical role is that mutations of neurexin and neuroligin genes have been found in a small subset of patients with autism. However, even though neurexin-neuroligin interactions can organize synapses in culture, it remains unclear whether this is their primary role in vivo. Genetic deletion of neurexins or neuroligins has little effect on synapse size or number. Thus other transsynaptic ligand-receptor pairs may organize synaptic differentiation in the brain, with neuroligins and neurexins consolidating

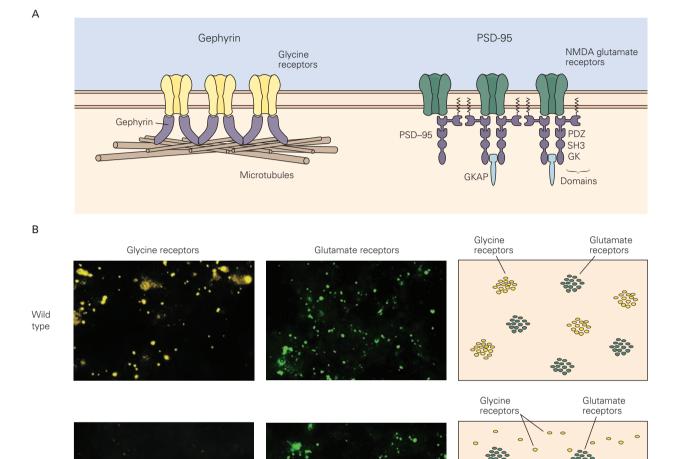

Figure 55–16 Cytoplasmic proteins are responsible for clustering of neurotransmitter receptors at central synapses.

Gephyrin mutant

A. Glycine receptors are linked to microtubules by gephyrin, whereas NMDA-type glutamate receptors are linked to each other and to the cytoskeleton by PSD-95 related molecules. The PSD family of molecules contain PDZ domains that interact with a variety of synaptic proteins to assemble signaling

complexes. Other PDZ-containing proteins interact with AMPAtype and metabotropic glutamate receptors (see Chapter 10).

B. In gephyrin mutant mice glycine receptors do not cluster at synaptic sites on spinal motor neurons and the animals show spasticity and hyperreflexia. In the same neurons glutamate receptor clusters are unaffected. (Adapted, with permission, from Feng et al. 1998.)

these synapses at a later time and specifying their particular properties. Candidate synaptic organizers include adhesion molecules of the cadherin and immunoglobulin superfamilies, as well as ephrins and Ephkinases, and soluble members of the fibroblast growth factor and Wnt families of morphogens. Which of the many proteins capable of influencing synaptic differentiation in culture are actually crucial for synapse formation in vivo remains to be determined.

Glial Cells Promote Synapse Formation

We have focused on the pre- and postsynaptic partners at synapses, but the organization of synapses involves a third cellular element: glial cells. Schwann cells are the glia at neuromuscular junctions, and astrocytes are the glia at central synapses. Neurons form few synapses when cultured in isolation but many when glia are present (Figure 55–18A).

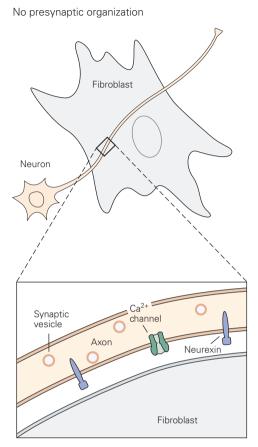

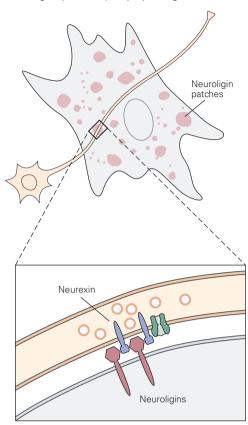

Figure 55–17 Macromolecular complexes link pre- and postsynaptic membranes at central synapses. Interactions between neurexins and neuroligins promote synaptic differentiation. When brain neurons are cultured with cells that express neuroligin, those segments of the axon that contact these cells

Neuroligins promote presynaptic organization

form presynaptic specializations, marked by clustered neurexin, Ca²⁺ channels, and synaptic vesicles. Neurons grown with control cells lacking neuroligins lack such presynaptic specializations. (Adapted, with permission, from Scheiffele et al. 2000 and Graf et al. 2004.)

Glial cell surface and secreted molecules are both required for optimal synapse formation. Several glial-derived molecules that enhance synapse function have been isolated. One in particular is a large matrix protein, thrombospondin, and another a lipid, cholesterol. Others presumably remain to be discovered.

Some Synapses Are Eliminated After Birth

In adult mammals each muscle fiber bears only a single synapse. However, this is not the case in the embryo. At intermediate stages of development several axons converge on each myotube and form synapses at a common site. Soon after birth all inputs but one are eliminated.

The process of synapse elimination is not a consequence of neuronal death. It occurs long after the period of naturally occurring cell death (see Chapter 53). Each

motor axon withdraws branches from some muscle fibers but strengthens its connections with others, thus focusing its increasing capacity for transmitter release on a decreasing number of targets. Moreover, axonal elimination is not targeted to defective synapses; all inputs to a neonatal myotube are morphologically and electrically similar, and each can activate the postsynaptic cell (Figure 55–19).

What is the purpose of the transient stage of polyneuronal innervation? One possibility is that it ensures that each muscle fiber is innervated. A second is that it allows all axons to capture an appropriate set of target cells. A third, intriguing idea is that synapse elimination provides a means by which activity can change the strength of specific synaptic connections. We begin to explore this idea in Chapter 56.

Like synapse formation, synapse elimination results from intercellular interactions. Every muscle

- B. Neurons cultured with astrocytes form more synapses, as assessed by expression of synaptic proteins (yellow dots). (Reproduced, with permission, from Ben A. Barres.)
- **C.** Retinal neurons cultured with astrocytes form a greater number of synapses, as shown by increased transmitter release.
- **D.** Synapse formation is enhanced in the presence of astrocytes by three measures.

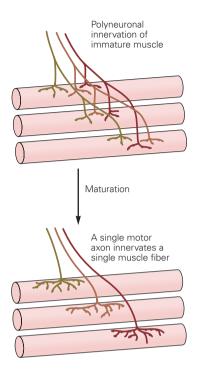

Figure 55–19 Some neuromuscular synapses are eliminated after birth. Early in the development of the neuromuscular junction each muscle fiber is innervated by several motor axons. After birth all motor axons but one withdraw from each fiber and the surviving axon becomes more elaborate. Synapse elimination occurs without any overall loss of axons—axons that "lose" at some muscle fibers "win" at others.

fiber ends up with exactly one input: None have zero, and very few have more than one. It is difficult to imagine how this could occur without feedback from the muscle cell. Moreover, the axons that remain after partial denervation at birth have a larger number of synapses than they did initially. Thus synapse elimination appears to be a competitive process.

What drives the competition and what is the reward? There is good evidence that neural activity plays a role: Paralysis of muscle reduces competition, whereas direct stimulation enhances it. These findings show that activity is involved, but they do not show that activity determines the outcome of the process, as all axons are affected similarly. Because the essence of the competitive process is that some synapses gain territory at the expense of others, differential activity among axons may be a determinant of axon winners and losers. Changing the activity of only a subset of axons in a living animal has been a technical challenge, but genetic approaches have made this possible in mice. In fact, when the activity of one of the inputs to

a muscle fiber is decreased, that axon is highly likely to withdraw.

If the more active axon wins the competition, there is a new problem. Because all synapses made by an axon have the same activity pattern, one might predict that the least active axon in the muscle would eventually lose all of its synapses and the most active would retain all of its synapses. Yet this does not happen. Instead, all axons win at some sites and lose at others, so that every axon ends up innervating a substantial number of muscle fibers.

One possible resolution to this paradox is that the outcome of competition may not be determined by the number of synaptic potentials from the winning axon at a synapse but rather by the total amount of synaptic input that the axon provides to the muscle—a product of the number of impulses and the amount of transmitter released per impulse. In this case an axon that loses at several synapses might redistribute its resources (for example, synaptic vesicles) so that the remaining terminals would be strengthened and more likely to win at their synapses. Conversely, an axon that wins many competitions might find itself with insufficient vesicles to generate large synaptic potentials, and would eventually lose to competitors at some synapses. In this way the number of muscle fibers innervated by individual axons would vary little among axons, as observed.

If activity drives the competition, what is the object of the competition? One idea is that the mechanisms are similar to those that determine whether neurons live or die. The muscle might produce limited amounts of a trophic substance for which the axons compete. As the winner grows it either deprives the loser of its sustenance or gains enough strength to mount an attack on its competitor. Alternatively, the muscle might release a toxic or punitive factor. In these scenarios, although the muscle does contribute a factor in the competition, the outcome is entirely dependent on differences between axons. These differences could be related to activity. The more active axon might be better able to take up trophic factor or resist a toxin. Such positive and negative competitive interactions have been demonstrated at nerve-muscle synapses in culture although not in vivo.

The muscle, however, could play a selective role in synapse elimination rather than just providing a broadly distributed signal. This idea is based on studies in which individual neuromuscular junctions were observed at close intervals during the process of synapse elimination. Acetylcholine receptors and components of the postsynaptic cytoskeleton begin to disappear from parts of the maturing neuromuscular junction before nerve terminals withdraw. This suggests that

differences in activity among competing axons may elicit different responses in postsynaptic ACh receptors. For example, the more active axon might trigger a signal from the muscle fiber that strengthens its adhesive interactions with the synaptic cleft, whereas the less active axon might elicit a signal that weakens those interactions.

The complexity of the brain makes direct demonstration of synapse elimination problematic, but electrophysiological evidence from many parts of the central nervous system indicates that synapse elimination is widespread. In autonomic ganglia synapse elimination has been documented directly and their rules seem similar to that found at neuromuscular junctions. Individual axons withdraw from some post-synaptic cells while simultaneously increasing the size of the synapses they form with other neurons.

An Overall View

The formation of synapses completes the hardwiring of the nervous system. To form a functional network, synaptic connections must be exquisitely specific: nerve terminals must recognize the proper target cell from numerous potential partners and often even a specific portion of the target cell's surface. Specificity starts with molecular recognition between partners and is enhanced by patterns of electrical activity.

The requirements for the synapse are stringent. The postsynaptic membrane must be responsive to the neurotransmitter that the nerve terminal releases. The apposition of pre- and postsynaptic elements must be precise at a molecular level, so that responses can occur on a time scale of milliseconds. And synaptic structure must be sufficiently stable to last a lifetime, yet sufficiently plastic to change with experience.

To meet these demands, synaptogenesis needs to be a highly interactive process. Although the pre- and postsynaptic cells can each synthesize synaptic components on their own, they exchange numerous signals to coordinate their activities spatially and temporally. In this chapter we have illustrated these interactions primarily with a focus on the neuromuscular junction. Motor nerve terminals use a combination of electrical and chemical signals to sculpt the postsynaptic apparatus of the muscle fiber. One key signal is agrin, which acts with the neurotransmitter ACh to sculpt the postsynaptic membrane. In turn, the muscle fiber provides signals that organize synaptic specialization in the nerve terminal, signals that include both soluble trophic factors and matrix-associated proteins such as the laminins.

Although central synapses are less accessible, it is becoming clear that they develop by the same general rules as neuromuscular junctions. Some developmentally important molecules found at the neuromuscular junction also regulate differentiation of central synapses, but the latter also use different signals such as the neurexins and neuroligins.

Finally, some of the synapses formed by a particular axon are eliminated, while others prosper. Axons begin by making small synapses on many targets, and end up with large synapses on relatively few targets. This rearrangement is often triggered by activity providing a means through which experience, translated into neural impulses, can modify neural circuits during early life.

An Overall View

THE HUMAN NERVOUS SYSTEM IS FUNCTIONAL at birth: Newborn babies can see, hear, breathe, and suckle. However, the capabilities of human infants are quite rudimentary compared to those of other species. Wildebeest calves can stand and run within minutes of birth, and many birds can fly shortly after they hatch from their eggs. In contrast, a human baby cannot lift its head until it is 2 months old, cannot bring food to its mouth until it is 6 months old, and cannot survive without parental care for a decade.

What accounts for the delayed maturation of our motor, perceptual, and cognitive abilities? One main factor is that the embryonic connectivity of the nervous system, discussed in Chapters 52 through 55, is only a "rough draft" of the neural circuits that exist in our adult selves. After birth, embryonic circuits are refined by sensory stimulation—our experiences. This two-part sequence—genetically determined connectivity followed by experience-dependent reorganization—is a common feature of mammalian neural development, but in humans the second phase is especially prolonged.

At first glance this delay in human neural development might seem dysfunctional. Although it does exact a toll, it also provides an advantage. Because our mental abilities are shaped largely by experience, we gain the ability to custom fit our nervous systems to our individual bodies and unique environments. It could be argued that it is not the large size of the human brain but rather its experience-dependent maturation that makes our mental capabilities superior to those of other species.

The plasticity of the nervous system in response to experience endures throughout life. Nevertheless, periods of heightened susceptibility to modification, known as *sensitive periods*, occur at particular times in development. In some cases the adverse effects of deprivation or atypical experience early in life cannot easily be reversed by providing appropriate experience at a later age. Such necessary periods of development are referred to as *critical periods*. As we shall see, new discoveries are blurring the distinction between sensitive and critical periods, so we will use the term critical periods to refer to both.

Critical periods can most easily be appreciated from the perspective of behavior—the capacity to perceive the world around us, to learn a language, or to form strong social relationships. A 5-year-old child can quickly and effortlessly learn a second language, whereas a 15-year-old adolescent may become fluent but is likely to speak with an accent, even if he lives to be 90 years old. Likewise, when a cataract that deprives a child of vision is removed in early childhood, there are no lasting effects of the cataract, but when the surgery occurs at the age of 10 years, she is unlikely ever to have normal visual acuity. In each of these cases relevant experience must occur within a critical period if behavior is to develop normally.

The process of learning is also influenced by critical periods. One of the most striking illustrations of a lifelong behavior established during a critical period is imprinting, a form of learning in birds. Just after hatching, birds become indelibly attached, or imprinted, to a prominent moving object in their environment, typically their mother. The process of imprinting is important for the protection of the hatchling. Although the attachment is acquired rapidly and persists, imprinting can only occur during a critical period soon after hatching—in some species only a few hours. Thus postnatal development of the nervous system can be viewed as a series of critical periods.

We begin this chapter by examining the evidence that early experience shapes a range of human mental capacities, from our ability to make sense of what we see to our ability to engage in appropriate social interactions. To illustrate the neural basis of these experiential effects we describe the role of experience in the development of the visual system in experimental animals. Studies of the development of the visual system have provided our most detailed understanding of how experience shapes neural circuitry throughout the brain. We will see that experience is needed to refine patterns of synaptic connections and to stabilize these patterns once they have formed. Finally, we will consider recent evidence that critical periods may be less restrictive than once thought; in some cases they can be extended or "reopened".

Understanding experience-dependent plasticity and the extent to which critical periods can be reopened in adulthood has important practical consequences. First, much educational policy is based on the idea that early experience is crucial, so it is important to know exactly when a particular form of enrichment will be optimally beneficial. Second, medical treatment of many childhood conditions, such as congenital cataracts, is now predicated on the idea that early intervention is imperative if long-lasting deficits are to be avoided. Third, there is increasing concern that some behavioral disorders, such as autism, may be caused by impaired reorganization of neural circuits during critical periods. Finally, the possibility of reopening critical periods in adulthood is leading to new therapeutic approaches to neural insults such as stroke that previously were thought to have irreversible consequences.

Development of Human Mental Function Is Influenced by Early Experience

Early Experience Has Lifelong Effects on Social Behaviors

The conclusion that certain social or perceptual experiences are important for human development was first arrived at through studies of children who had been deprived of these experiences early in life. In rare cases children abandoned in the wild and later returned to human society have been studied. As might be expected, these children were socially maladjusted. Surprisingly, however, the defects proved to be generally irreversible.

In the 1940s the psychoanalyst René Spitz provided more systematic evidence that early interactions with other humans are essential for normal social development. Spitz compared the development of infants raised in a foundling home with the development of infants raised in a nursing home attached to a women's prison. Both institutions were clean and both provided adequate food and medical care. The babies in the prison nursing home were all cared for by their mothers, who, although in prison and away from their families, tended to shower affection on their infants in the limited time allotted to them each day. In contrast, infants in the foundling home were cared for by nurses, each of whom was responsible for several babies. As a result, children in the foundling home had far less contact with other humans than did those in the prison's nursing home.

The two institutions also differed in another respect. In the prison nursing home the cribs were

open, so that the infants could readily watch other activities in the ward; they could see other babies play and observe the staff go about their business. In the foundling home the bars of the cribs were covered by sheets that prevented the infants from seeing outside. In reality, the babies in the foundling home were living under conditions of severe sensory and social deprivation.

Groups of newborn infants at the two institutions were followed through their early years. At the end of the first 4 months the infants in the foundling home fared better on several developmental tests than those in the prison nursing home, suggesting that intrinsic factors did not favor the infants in the prison nursing home. But by the end of the first year the motor and intellectual performance of the children in the foundling home had fallen far below that of children in the prison nursing home. Many of the children in the foundling home had developed a syndrome that Spitz called hospitalism and is now often called anaclitic depression. These children were withdrawn and displayed little curiosity or gaiety. Moreover, their defects extended beyond the emotional and cognitive. They were especially prone to infection, implying that the brain exerts complex controls over the immune system as well as behavior. By their second and third years, children in the prison nursing home were similar to children raised in normal families at home—they were agile, had a vocabulary of hundreds of words, and spoke in sentences. In contrast, the development of children in the foundling home was still further delayed—many were unable to walk or to speak more than a few words.

More recent studies of other similarly deprived children have confirmed these conclusions and shown that the defects are long-lasting. Longitudinal studies of orphans who were raised for several years in large impersonal institutions with little or no personal care, then adopted by caring families, have been especially revealing. Despite every effort of the adoptive parents, many of the children were never able to develop appropriate, caring relationships with family members or peers (Figure 56–1A). More recent imaging studies have revealed defects in brain structure correlated with, and presumably due to, this deprivation (Figure 56–1B).

As compelling as these studies on humans are, it is difficult to derive definitive conclusions. An influential set of studies that extended the analysis of social behavior to monkeys was carried out in the 1960s by two psychologists, Harry and Margaret Harlow. The Harlows reared newborn monkeys in isolation for 6 to 12 months, depriving them of contact with their mothers, other monkeys, or people. At the end of this period the monkeys were physically healthy but behaviorally

devastated. They crouched in a corner of their cage and rocked back and forth like autistic children (Figure 56–1C). They did not interact with other monkeys, nor did they fight, play, or show any sexual interest. Thus a 6-month period of social isolation during the first 18 months of life produced persistent and serious disturbances in behavior. By comparison, isolation of an older animal for a comparable period was found to be without such drastic consequences. These results confirmed, under controlled conditions, the critical influence of early experience on later behavior. For ethical reasons, these studies would not be possible today.

Development of Visual Perception Requires Visual Experience

The dramatic dependence of the brain on experience and the ability of that experience to shape perception is evident in people born with cataracts. Cataracts are opacities of the lens that interfere with the optics of the eye but not directly with the nervous system; they are easily removed surgically. In the 1930s it became apparent that patients who had congenital binocular cataracts removed after the age of 10 years had permanent deficits in visual acuity and had difficulties perceiving shape and form, a condition called *amblyopia*. In contrast, when cataracts that develop in adults are removed decades after they form, normal vision returns immediately.

Likewise, children with *strabismus* (crossed eyes) do not have normal depth perception (*stereopsis*), an ability that requires the two eyes to focus on the same location at the same time. They can acquire this ability if their eyes are aligned surgically during the first few years of life, but not if surgery occurs later in adolescence. As a result of these observations, congenital cataracts are now usually removed, and strabismus is corrected surgically, in early childhood. Over the past few decades researchers have elucidated structural and physiological underpinnings of these critical periods.

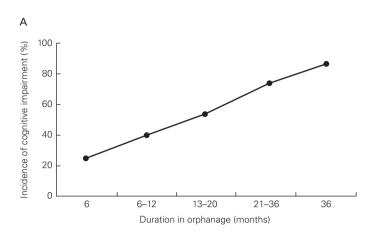

Development of Binocular Circuits in the Visual Cortex Depends on Postnatal Activity

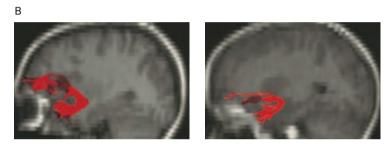

Because sensory experience of the world is transformed into patterns of electrical activity in the brain, one might imagine that electrical signals in neural circuits affect the brain's circuitry. But is this true? And if it is true, what changes occur and how does activity trigger them?

Our most detailed understanding of these links comes from studies of the neural circuits that mediate

Figure 56–1 Early social deprivation has a profound impact on later brain structure and behavior.

- A. Neurocognitive dysfunction is evident in children raised under conditions of social deprivation in orphanages. The incidence of cognitive impairment increases with the duration of stay in the orphanage. (Reproduced, with permission, from Behen et al. 2008.)
- B. Diffusion tensor magnetic resonance imaging (MRI) scans show a well-developed and robust uncinate fasciculus (red region) in a normal child (left), whereas in a socially deprived child (right) it is thin and poorly organized. (Reproduced, with permission, from Eluvathingal et al. 2006.)
- C. Early social interactions impact later social behavior patterns. Monkeys reared in the presence of their siblings acquire social skills that permit effective interactions in later life (left). A monkey reared in isolation never acquires the capacity to interact with others, and remains secluded and isolated in later life (right). (Adapted, with permission, from Harry F. Harlow, University of Wisconsin.)

binocular vision. The key figures in the early phases of this work were David Hubel and Torsten Wiesel, who undertook a set of studies on cats and monkeys to investigate how experience affects the structural and functional organization they had delineated (Figure 56–2).

Visual Experience Affects the Structure and Function of the Visual Cortex

In one influential study Hubel and Wiesel raised a monkey from birth to 6 months of age with one eyelid sutured shut, thus depriving the animal of vision in that eye. When the sutures were removed it became clear that the animal was blind in the deprived eye. They then performed electrophysiological recordings

from cells along the visual pathway to determine where the defect arose. They found that retinal ganglion cells in the deprived eye, as well as neurons in the lateral geniculate nucleus that receive input from the deprived eye, responded well to visual stimuli and had essentially normal receptive fields.

In contrast, cells in the visual cortex were fundamentally altered. In the cortex of normal animals most neurons are binocularly responsive. In animals that had been monocularly deprived for the first 6 months, most cortical neurons did not respond to signals from the deprived eye (Figure 56–3). The few cortical cells that were responsive were not sufficient for visual perception. Not only had the deprived eye lost its ability to drive most cortical neurons, but this loss was permanent and irreversible.

Hubel and Wiesel went on to test the effects of visual deprivation imposed for shorter periods and at different ages. They obtained three types of results, depending on the timing and duration of the deprivation. First, monocular deprivation for a few weeks during the first 2 postnatal months led to loss of cortical responses from the deprived eye that was reversible after the eye had been opened, especially if the opposite eye was then closed to encourage use of the initially deprived eye. Second, monocular deprivation for a few weeks during the next months also resulted in a substantial loss of cortical responsiveness to signals from of the deprived eye, but in this case the effects were irreversible. Finally, deprivation in adults, even for periods of many months, had no effect on the responses of cortical cells to signals from the deprived eve or on visual perception. These results demonstrated that the cortical connections that control visual perception are established within a critical period of early development.

Are there structural correlates of these functional defects? To address this question we need to recall three basic facts about the anatomy of the visual cortex. First, inputs from the two eyes remain segregated in the lateral geniculate nucleus. Second, the geniculate inputs carrying information from the two eyes to the cortex terminate in alternating columns, termed *ocular dominance columns*. Third, lateral geniculate axons terminate on neurons in layer IVC of the primary visual

cortex; convergence of input from the two eyes on a common target cell occurs at the next stage of the pathway, in cells above and below layer IVC (Figure 56–2).

To examine whether the architecture of ocular dominance columns depends on visual experience early in postnatal life, Hubel and Wiesel deprived newborn animals of vision in one eye and then injected a labeled amino acid into the normal eye. The injected label was incorporated into proteins in retinal ganglion cell bodies, transported along the retinal axons to the lateral geniculate nucleus, transferred to geniculate neurons, and then transported to the synaptic terminals of these axons in the primary visual cortex. After closure of one eye the columnar array of synaptic terminals relaying input from the deprived eye was reduced, whereas the columnar array of terminals relaying input from the normal eye was expanded (Figure 56–4). Thus sensory deprivation early in life alters the structure of the cerebral cortex.

How are these striking anatomical changes brought about? Does sensory deprivation alter ocular dominance columns after they have been established, or does it interfere with their formation? It is now clear that the mature pattern of ocular dominance columns in monkeys is not achieved until 6 weeks after birth (Figure 56–5). Only at this time do the terminals of fibers from the lateral geniculate nucleus become completely segregated in the cortex (Figure 56–6). Because the inputs are not well segregated at the time that

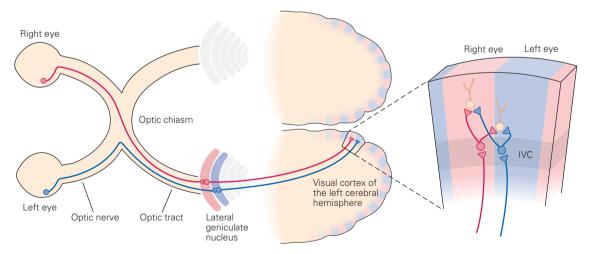

Figure 56–2 Afferent pathways from the two eyes project to discrete columns of neurons in the visual cortex. Retinal ganglion neurons from each eye send axons to separate layers of the lateral geniculate nucleus. The axons of neurons in the lateral geniculate nucleus project to neurons in layer IVC of the primary visual cortex. Neurons in layer IVC are organized

in alternating sets of ocular dominance columns; each column receives input from only one eye. The axons of the neurons in layer IVC project to neurons in adjacent columns as well as to neurons in the upper and lower layers of the same column. As a result, most neurons in the upper and lower layers of the cortex receive information from both eyes.

visual deprivation exerts its effects, we can conclude that the deprivation perturbs the segregation of the inputs. We will see later that the remodeling of thalamic axonal arbors contributes to the perturbation of cortical columns.

Patterns of Electrical Activity Organize Binocular Circuits in the Visual Cortex

What determines the extent of ocular dominance columns? The crucial factor may be the existence of minor differences in the proportion of inputs from each eye that converge on common target cells at birth. If by chance the fibers conveying input from one eye are initially more numerous in one local region of cortex, those axons may have an advantage.

How might this occur? An attractive idea, based on a theory first proposed in the 1940s by Donald Hebb, is that connections are strengthened when pre- and post-synaptic elements at a synapse are active together. In the case of binocular interactions, neighboring axons from the same eye tend to fire in synchrony because they are activated by the same visual stimulus at any instant. The synchronization of their firing means that

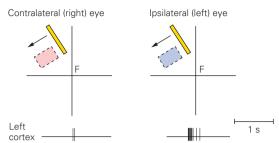

Figure 56–3 Responses of neurons in the primary visual cortex of a monkey to visual stimuli. (Adapted, with permission, from Hubel and Wiesel 1977.)

A. A diagonal bar of light is moved leftward across the visual field, traversing the receptive fields of a binocularly responsive cell in area 17 of visual cortex. Receptive fields measured through the right and left eye are drawn separately. The receptive fields of the two cells are similar in orientation, position, shape, and size, and respond to the same form of stimulus. Recordings (below) show that the cortical neuron responds more effectively to input from the ipsilateral eye. (F, fixation point.)

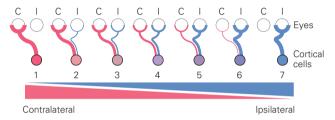

B. The responses of single cortical neurons in area 17 can be classified into seven groups. Neurons receiving input only from the contralateral eye (C) fall into group 1, whereas neurons that receive input only from the ipsilateral eye (I) fall into group 7. Other neurons receive inputs from both eyes, but the input from one eye may influence the neuron much more than the other (groups 2 and 6), or the differences may be slight (groups 3 and 5). Some neurons respond equally to input from both eyes (group 4). According to these criteria, the cortical neuron shown in part A falls into group 6.

C. Responsiveness of neurons in area 17 to stimulation of one or the other eye. The upper plot shows the responses of more than 1,000 neurons in area 17 in the left hemisphere of normal adult and juvenile monkeys. Neurons in layer IV that normally receive only monocular input have been excluded. The lower plot shows the responses of neurons in the left hemisphere of a monkey in which the contralateral (right) eye was closed from the age of 2 weeks to 18 months and then reopened. Most neurons respond only to stimulation of the ipsilateral eye.

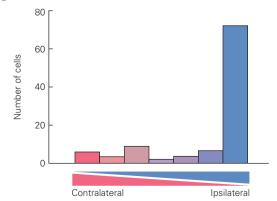

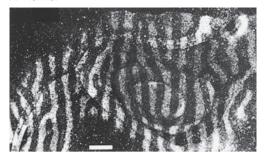

Figure 56–4 Visual deprivation of one eye during a critical period of development reduces the width of the ocular dominance columns for that eye. (Scale bars = 1 mm.) (Adapted, with permission, from Hubel et al. 1977.)

A. A tangential section through area 17 of the right hemisphere of a normal adult monkey, 10 days after the right eye was injected with a radiolabeled amino acid. Radioactivity is localized in stripes (white areas) in layer IVC of the visual cortex, indicating areas of termination of the axons from the lateral geniculate nucleus that carry input from the injected eye. The alternating unlabeled (dark) stripes correspond to regions of termination of the axons carrying signals from the uninjected eye. Labeled and unlabeled stripes are of equal width.

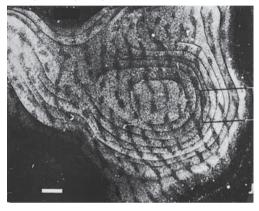

B. A comparable section through the visual cortex of an 18-month-old monkey whose right eye had been surgically closed at 2 weeks of age. Label was injected into the left eye. The wider white stripes are the labeled terminals of afferent axons carrying signals from the open (left) eye; the narrow dark stripes are terminals of axons with input from the closed (right) eye.

C. A section comparable to that in part B from an 18-month-old animal whose right eye had been shut at 2 weeks. Label was injected into the right eye, giving rise to narrow white stripes of labeled axon terminals and wide dark stripes of unlabeled terminals.

they cooperate in the depolarization and excitation of a target cell. This cooperative action maintains the viability of those synaptic contacts at the expense of the noncooperating synapses.

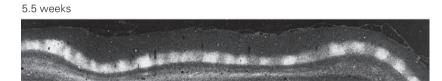

Cooperative activity promotes branching of axons and thus creates the opportunity for the formation of additional synaptic connections with cells in the target region. At the same time, the strengthening of synaptic contacts made by the axons of one eye will impede the growth of synaptic inputs from the opposite eye. In this sense fibers from the two eyes may be said to compete

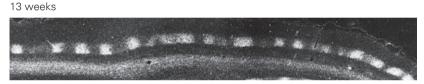

for a target cell. Together, cooperation and competition between axons ensure that two populations of afferent fibers will eventually innervate distinct regions of the primary visual cortex with little local overlap.

Competition and cooperation are not simply the outcome of neural activity per se, or of differences in absolute levels of activity among axons. Instead, they appear to depend on precise temporal patterns of activity in the competing (or cooperating) axons. The principle was dramatically illustrated by Hubel and Wiesel in a set of studies that examined stereoscopic

Figure 56-5 The development of ocular dominance columns. Autoradiographs of four stages in the postnatal development of ocular dominance columns in the visual cortex in a cat. The images show horizontal sections through columns in the cortex ipsilateral to an eye that was injected with a radiolabeled amino acid. The cells in the lateral geniculate nucleus that receive input from the injected eye become labeled by transneuronal transport. At 15 days after birth the terminals of labeled fibers are spread in a relatively uniform manner along layer IV and are intermingled with those of unlabeled fibers that convey signals from the contralateral eve. At 3 and 5.5 weeks some segregation of the terminals is visible, but only as modest differences in labeling density. At 13 weeks the borders of the labeled bands become more sharply defined as the fibers conveying inputs from each eye segregate. (Adapted, with permission, from LeVay, Stryker, and Shatz 1978.)

2 weeks 3 weeks

1 mm

vision—the perception of depth. The brain normally computes depth perception by comparing the disparity in retinal images between the two eyes. When the eyes are improperly aligned, this comparison cannot be made and stereoscopy is impossible. Such misalignments occur in children who are "cross-eyed," or strabismic. As noted, this condition can be surgically repaired, but unless the surgery occurs during the first few years of life, the children forever remain incapable of stereoscopy.

Hubel and Wiesel examined the impact of strabismus on the organization of the visual system in cats. To render cats strabismic, the tendon of an extraocular muscle was severed in kittens. Both eyes remained fully functional but misaligned. Inputs from the two eyes that converged on a binocular cell in the visual cortex now carried information about different stimuli in slightly different parts of the visual field. As a result, cortical cells became monocular, driven by input from one eye or the other but not both (Figure 56–7). This finding suggested to Hubel and Wiesel that disruption of the synchrony of inputs led to competition rather than cooperation, so that cortical cells came to be dominated by one eye, presumably the one that had dominated it very slightly at the outset.

These physiological studies led investigators to test whether pharmacological blockade of electrical activity in retinal ganglion cells could affect neural connectivity in the visual system. Activity was blocked by injecting each eye with tetrodotoxin, a toxin that selectively blocks voltage-sensitive Na⁺ channels. Signals from the two eyes were generated separately by direct electric stimulation of the bilateral optic nerves. In kittens ocular dominance columns are not established if activity in retinal ganglion neurons is blocked before the critical period of development. When the two optic nerves are stimulated synchronously, ocular dominance columns still fail to form. Only when the optic nerves are stimulated asynchronously are ocular dominance columns established.

If the development of ocular dominance columns indeed depends on competition between afferent fibers, might it be possible to induce the formation of columns where they normally are not present, simply by establishing competition between two sets of axons? This radical possibility was tested in frogs, where retinal ganglion neurons from each eye project only to the contralateral side of the brain. In normal frogs afferent fibers from the two eyes do not compete for the same cortical cells, so there is no columnar segregation

of afferent inputs. To generate competition a third eye was transplanted early in larval development into a region of the frog's head near one of the normal eyes. The retinal ganglion neurons of the extra eye extended axons to the contralateral optic tectum. Remarkably, axon terminals from the transplanted and normal eyes segregated, generating a pattern of regular alternating columns (Figure 56–8).

This finding suggested that competition between two sets of afferent axons for the same population of cortical neurons drives their segregation into distinct target territories. The columnar segregation of retinal inputs in the frog brain is dependent on synaptic activity, presumably at the synapses between retinal axons and tectal neurons. Thus neural activity has powerful roles in fine-tuning visual circuits.

Reorganization of Visual Circuits During a Critical Period Involves Alterations in Synaptic Connections

The pioneering work of Hubel, Wiesel, and their colleagues showed that early experience is a critical

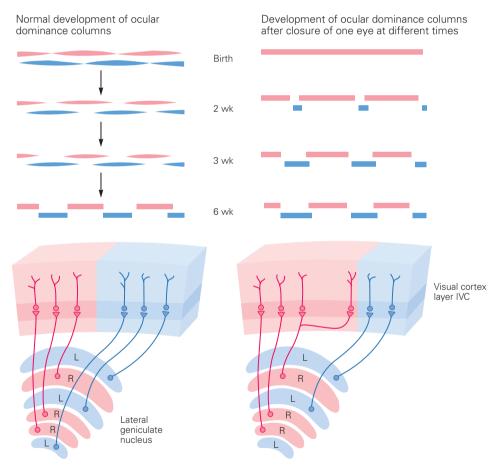

Figure 56–6 The effects of eye closure on the formation of ocular dominance columns. The top diagrams show the gradual segregation of the terminals of lateral geniculate afferents in layer IVC of the visual cortex under normal conditions (left) and when one eye is deprived of stimulation (right). The blue domains represent the areas of termination of inputs from one eye, the red domains are those of the other eye. The lengths of the domains represent the density of the terminals at each point along layer IVC. For clarity the columns are shown here as one above the other, whereas in reality they are side by side

in the cortex. During normal development layer IVC is gradually divided into alternating sites of input from each eye. The consequences of depriving sight in one eye depend on the timing of eye closure. Closure at birth leads to dominance by the open eye (red) because at this point little segregation has occurred. Closure at 2, 3, and 6 weeks has a progressively weaker effect on the formation of ocular dominance columns because the columns become more segregated with time. (Adapted, with permission, from Hubel, Wiesel, and LeVay 1977.)

B. In strabismic animals left and right eye domains are more sharply defined, an indication of the paucity of binocular regions. (Reproduced, with permission, from Löwel 1994.)

C. Strabismic animals have fewer binocularly tuned neurons in the visual cortex. (Reproduced, with permission, from Hubel and Wiesel 1965.) prerequisite for the emergence of normal structure and function in the visual cortex. However, despite four decades of research, many questions about the cellular and molecular mechanisms that underlie the critical period have remained unanswered. Hubel, Wiesel, and their disciples studied cats and monkeys, in which manipulations of cells and molecules are difficult. Recently, many investigators have begun to address these issues in mice because they are more amenable to mechanistic analysis.

Reorganization Depends on a Change in the Balance of Excitatory and Inhibitory Inputs

When one eye is closed or patched, the cortex no longer receives input from that eye. If the loss of input is prolonged for a few days before the eye is reopened, the cortex cannot be activated by input from the formerly deprived eye. Nor can the cells of the cortex be activated by direct stimulation of the corresponding optic nerve.

What converts this early loss of functional input into a permanent alteration of functional capability? One idea is that thalamic axons carrying information from the deprived eye lose their ability to activate cortical neurons. A decrease in efficacy of the thalamocortical synapse may contribute to this effect, but this is not the whole story. In cats and monkeys each thalamic axon carries input from only one eye (Figure 56–2). Because loss of responsiveness to the deprived eye occurs only if the other eye remains active, one might imagine that the earliest changes would occur where inputs from the two eyes converge on binocular cells. Local circuits connect the targets of the monocular thalamic inputs in layer IV to the binocular neurons in layers II/III and V. The first physiological changes following closure of one eye occur in layers II/III and V, not in layer IV. This implies that the loss of cortical responsiveness to the deprived eye results from a circuit alteration rather than from a simple loss of input.

What changes in cell function account for these changes in circuitry? At least three have been proposed. First, excitatory synapses within the primary visual cortex may decrease in strength, perhaps by undergoing long-term depression (LTD) (see Chapter 66). In fact, direct recording from cortical neurons shows that LTD does occur soon after eye closure. Second, inhibitory synapses may become stronger, leading to a net decrease in the level of excitation of cortical neurons by inputs from the closed eye. Third, an increase in inhibition within the cortex may alter network properties in a more subtle way, such as tuning the circuit to favor LTD.

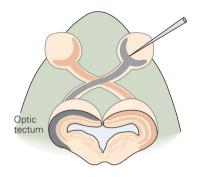

The involvement of inhibition has been demonstrated by studies in the binocular region of mouse

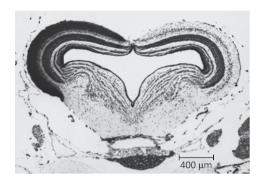

Figure 56–8 Ocular dominance columns can be experimentally induced in a frog by transplantation of a third eye. (Adapted, with permission, from Constantine-Paton and Law 1978.)

A. Three days before the transplant the right eye was injected with a radiolabeled amino acid. The autoradiograph in a coronal section of the hindbrain shows the entire superficial neuropil of the left optic lobe filled with silver grains, indicating the region occupied by synaptic terminals from the labeled (contralateral) eye.

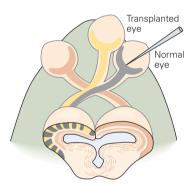

B. Some time after a third eye was transplanted near the normal right eye the right eye was injected with a radiolabeled amino acid. The autoradiograph shows that the left optic lobe receives inputs from both the labeled eye and the transplanted eye. The normally continuous synaptic zone of the contralateral eye has become divided into alternating dark and light zones that indicate the sites of inputs from each eye.

A Inputs are normally segregated in the tectum

B Transplanted eye induces ocular dominance columns

visual cortex. In mice, as in cats and monkeys, closure of the contralateral eye during the critical period for ocular dominance markedly shifts the preference of binocular neurons to inputs from the ipsilateral eye (Figure 56–9). Closure before or after the time of this normal critical period, however, fails to alter the preference of the neurons. Physiological studies have shown that monocular deprivation potentiates inhibitory feedback onto the neurons that the deprived eye normally excites. Moreover, the critical period in which monocular deprivation elicits changes in preference can be advanced using a genetic method to enhance gammaaminobutyric acid (GABA) signaling (Figure 56–10). Conversely, the period in which monocular deprivation enhances the preference for ipsilateral eye input can be delayed by delaying GABA signaling (Figure 56–10). Thus a balance of intracortical excitation and inhibition is required for reorganization during this critical period.

What explains the change in responsiveness? After one eye is closed responsiveness to the open eye increases. This increase involves enhanced efficacy of synaptic transmission, a process resembling long-term potentiation (see Chapters 66 and 67). Inputs firing together with the majority of their neighbors become

stronger, whereas inputs that are improperly matched to the majority pattern become weaker. This mechanism of reorganization conforms to Hebb's theory.

Postsynaptic Structures Are Rearranged During the Critical Period

What are the structural correlates of the physiological changes that result in altered responsiveness of the visual cortex to input from the closed and open eyes? Particular attention has been paid to dendritic spines as potential sites of plasticity.

Spines are small protrusions from the dendrites of many cortical neurons on which excitatory synapses form. They are dynamic structures, and their appearance and loss are thought to reflect the formation and elimination of synapses. Spine motility is especially marked during early postnatal development, and increases in spine dynamics and number have been associated with changes in behavior.

Striking alterations in the motility and number of dendritic spines on neurons in the mouse visual cortex are observed following closure of one eye. Two days after eye closure in young mice the motility and

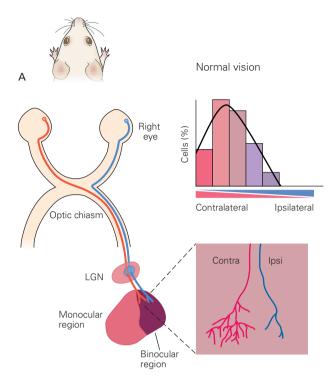

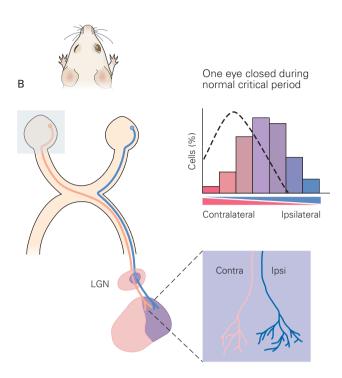

Figure 56–9 A critical period for ocular dominance plasticity is evident in mice. (Adapted, with permission, from Hensch et al. 2005.)

A. The visual cortex in mice contains a small region that receives thalamic (LGN) inputs from both eyes. In this binocular region most neurons are responsive to contralateral eye input, fewer respond to binocular inputs, and very few respond to ipsilateral eye input only.

B. When the contralateral eye has been closed during the normal critical period and then reopened, inputs from that eye are underrepresented and many more neurons respond to binocular or ipsilateral eye input. Eye closure before or after the time of the normal critical period does not elicit the same shift in responsiveness.

turnover of dendritic spines on neurons in the visual cortex increases, suggesting that synaptic connections are beginning to rearrange (Figure 56–11). A few days later the number of spines begins to change—the number of spines on the apical dendrites of pyramidal neurons initially decreases but after longer periods of deprivation increases again.

These alterations in spine motility and number can be correlated with three known features of the critical period. First, rather than occurring in layer IV, the changes occur primarily in superficial and deep layers of the cortex, where binocular cells lie. Second, they occur only in the portion of the visual cortex that normally receives binocular input. Third, they fail to occur following eye closure in adult mice (Figure 56–11).

Together these results support a model that links spine dynamics with critical period plasticity. According to this model, spine motility increases before physiological changes in responsiveness can be recorded. This condition may result from the imbalance of inputs

to binocular neurons from the open and closed eyes, and it may reflect the first stages in synaptic rearrangement. In turn, the loss of spines, and presumably of synapses, corresponds in time and space to the loss of input from the closed eye and may provide a structural basis for the permanence of this loss. The later growth of new spines occurs as or after responsiveness to the open eye increases, and may underlie the adaptive rearrangement that permits the cortex to make the best use of the input available to it.

Thalamic Inputs Are Also Remodeled

How are local changes in spines related to the largescale structural changes in ocular dominance columns shown in Figure 56–4? When developing axons from the lateral geniculate nucleus first reach the cortex, the terminal endings of several neurons overlap extensively. Each fiber extends a few branches over an area of the visual cortex that spans several future ocular dominance columns. As the cortex matures, axons retract some branches, expand others, and even form new branches (Figure 56–12A).

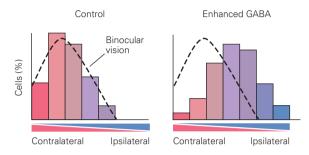

With time each geniculate neuron becomes connected almost exclusively to a group of neighboring cortical neurons within a single column. The arbors become segregated into columns through the pruning or retraction of certain axons and the sprouting of others. This dual process of axon retraction and sprouting occurs widely throughout the nervous system during development.

What happens after one eye is closed? Axons from a closed eye are at a disadvantage and a greater than normal proportion retract. At the same time, axons from the open eye sprout new terminals at sites vacated by fibers that would otherwise convey input from the closed eye (Figure 56-12B). If an animal is deprived of the use of one eye early during the critical period of axonal segregation, the normal processes of axon retraction and outgrowth are perturbed. In contrast, if an animal is deprived of the use of one eye only after the ocular dominance columns are almost fully segregated, axons conveying input from the open eye actually sprout collaterals in regions of the cortex that they had vacated earlier (see Figure 56–6).

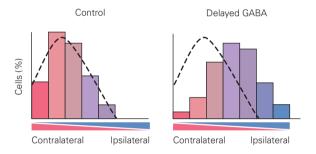

Initially it was believed that rearrangements of thalamocortical axons in monocularly deprived animals caused the changes in cortical responsiveness to the open and closed eyes. We now know, through electrophysiological recording and assays of spine dynamics described above, that physiological changes and synaptic alterations precede these large-scale axonal rearrangements. So rather than causing the physiological changes, axonal remodeling may contribute to making these changes enduring and irreversible. The question then becomes: How do alterations in synaptic structure and function within the cortex lead to alterations in the input?

One idea is that activity regulates the secretion of neurotrophic factors by cortical neurons. Such factors may then regulate survival of some neurons at the expense of others (see Chapter 53) or promote the expansion of some axonal arbors at the expense of others. One such factor, brain-derived neurotrophic factor (BDNF), is indeed synthesized and secreted by cortical neurons. Administering excess BDNF, or interfering with its receptor trkB, modifies the formation of ocular dominance columns. Nevertheless, interpreting the actions of these trophic factors is not straightforward. BDNF and trkB signaling affect the cortex in many ways, including enhancing the growth of thalamocortical axons. BDNF can also speed the maturation of inhibitory circuits, which, as noted above, can

Deprivation before normal critical period

Deprivation after normal critical period

Critical period for plasticity after monocular deprivation

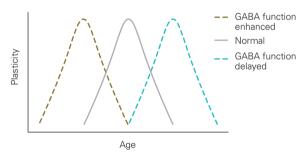

Figure 56–10 The timing of the critical period for ocular dominance plasticity in mice is sensitive to the level of GABAergic neurotransmission. Altering the status of GABA (γ -aminobutyric acid) synthesis and signaling shifts the period in which monocular deprivation can change the response properties of neurons in the visual cortex. Enhancing GABA signaling, through administration of benzodiazepines, shifts the critical period for monocular deprivation to an earlier developmental time. In contrast, delaying GABA signaling, by reducing GABA synthesis genetically and then administering benzodiazepines at a later time, shifts the critical period for monocular deprivation to a later developmental time. (Adapted, with permission, from Hensch et al. 1998.)

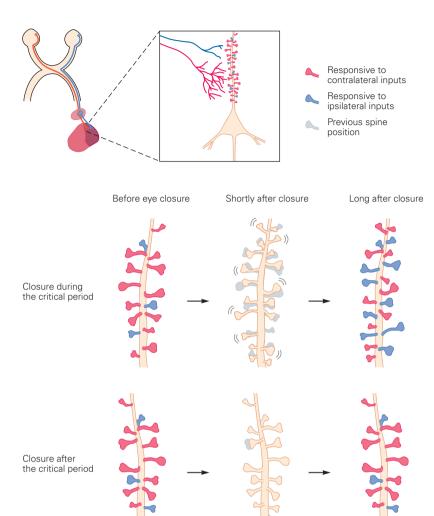

Figure 56–11 The motility of dendritic spines in the mouse visual cortex changes after one eye is closed. The dendrites of pyramidal neurons in the visual cortex have many spines, the density of which remains comparatively constant under normal conditions. Closure of one eye (contralateral in this example) during the critical period for binocular development enhances the motility of dendritic spines and over time results in an increase in the proportion of spines that receive synaptic input from the open eye. Similar changes in spine motility are not observed if the eye is closed after the critical period. (Reproduced, with permission, from Oray et al. 2004.)

influence plasticity. It remains unclear whether BDNF is a specific catalyst of the competition that preferentially promotes expansion of some arbors.

Synaptic Stabilization Contributes to Closing the Critical Period

A hallmark of critical periods is that the time interval in which experience affects the development of neural circuits is limited. What determines the timing of this remarkable biological response? To answer this question we must ask what opens the critical period and what closes it.

Opening of critical periods could result from maturation of systems required for plasticity. As we have mentioned, genetic studies indicate that maturation of inhibitory circuits in the visual cortex is required for initiation of the critical period for binocular development. Likewise, synapses that are modified by competitive interactions between the eyes, or by synchronous activity, may not undergo long-term potentiation or depression until they reach a sufficient level of maturity.

The factors that terminate the critical period have been studied in more detail. Since synapses and circuits are labile during critical periods, an obvious idea is that stabilizing factors bring this period of heightened plasticity to a close. The cellular and molecular landscape of the cortex changes in many ways as the brain matures, and several of these alterations may play roles. One parameter is the state of myelination of axons, which occurs around the time the critical period closes. Formation of myelin creates physical barriers to sprouting and axonal growth. Moreover, as discussed in detail in Chapter 57, myelin contains factors

such as Nogo and myelin-associated glycoprotein that actively inhibit growth of axons. In mutant mice lacking Nogo or one of its receptors, NogoR, the critical period remains open into adulthood, suggesting that the appearance of these receptors normally contributes to closing the critical period (Figure 56–13).

Another possible agent of closure is the perineuronal net, a web of glycosaminoglycans that wraps certain classes of inhibitory neurons. These nets form around the time that the critical period closes. Infusion of the enzyme chondroitinase, which digests perineuronal nets, maintains plasticity. Thus critical periods may close once molecular barriers to synaptic growth and rearrangement come into play.

Why should there be an end to critical periods? Would it not be advantageous for the brain to maintain its ability to remodel into adulthood? Perhaps not—the ability of our brain to adapt to variations in sensory input, to gradual physical growth (eg, increases in the distance between the eyes affecting binocular correspondence), and to various congenital disorders is a valuable asset. At an extreme, if one eye is lost it is advantageous to devote all available cortical real estate to the remaining eye. Conversely, one would not want wholesale reorganization, possibly accompanied by loss of skills and memories, if vision through one eye were lost temporarily in adulthood due to disease or injury. So enhancing plasticity during a critical period may represent an adaptive compromise between flexibility and stability.

Segregation of Retinal Inputs in the Lateral Geniculate Nucleus Is Driven by Spontaneous Neural Activity In Utero

Some of the principles of development of the visual cortex we have discussed also govern the development of the lateral geniculate nucleus. The arbors of retinal ganglion cells from the two eyes are segregated into alternating layers in this nucleus, much as the projections from this nucleus are segregated in alternating ocular dominance columns in the visual cortex (Figure 56–14).

In both structures individual axons at first form terminals in multiple domains (layers in the geniculate nucleus, columns in the cortex). Later the terminals become segregated by a process of refinement. As in the cortex, the segregation of the inputs from each eye can be disrupted by applying tetrodotoxin to the optic nerves, indicating that activity is essential for segregation. In the lateral geniculate nucleus, however, the segregation of inputs is complete before birth.

Since segregation of retinal inputs in the lateral geniculate nucleus occurs before birth, vision cannot drive the neural activity essential for segregation. It turns out that the axons of retinal neurons are spontaneously active in utero, well before the eyes open. Neighboring ganglion cells fire in synchronous bursts that last a few seconds, followed by silent periods that may last for minutes. Sampling the activity of retinal ganglion neurons across the entire retina revealed that

B Development after eye closure

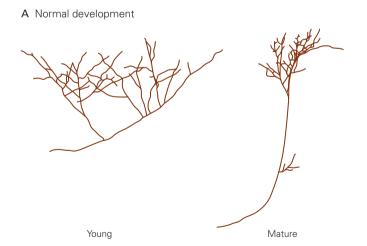

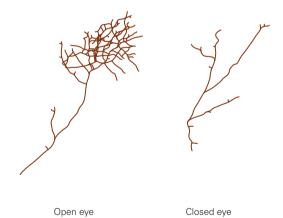

Figure 56–12 The branching of thalamocortical fibers in the visual cortex of kittens changes after the closure of an eye. (Adapted, with permission, from Antonini and Stryker 1993.)

A. During normal postnatal development the axons of lateral geniculate nucleus cells branch widely in the visual cortex. The branching eventually becomes confined to a small region.

B. After one eye is closed the terminal arbors of neurons in the pathway from that eye are dramatically smaller compared to those of the open eye.

these bursts propagate across much of the retina in a wave-like manner (Figure 56–15). This pattern of ganglion cell activity appears to be coordinated by excitatory inputs from amacrine cells in the overlying layer of the retina (see Figure 26–3).

The spontaneous, synchronous firing of a select group of ganglion neurons excites a local group of neurons in the lateral geniculate nucleus. Such synchronized activity appears to strengthen these synapses at the expense of other nearby synapses. The fact that retinal ganglion neurons are spontaneously active in utero is an important clue to the development of many pathways in the brain that are refined before they have the chance to respond to environmental stimulation.

Activity-Dependent Refinement of Connections Is a General Feature of Circuits in the Central Nervous System

We have seen that neural activity is critical for segregating axons from the two retinas into distinct layers in the lateral geniculate nucleus and then into distinct columns in the visual cortex. Is this a special case, or does activity also affect maturation elsewhere in the visual system, and even in other parts of the brain? Studies of many systems show that activity-dependent control of refinement is a general property of neural circuits in the mammalian brain.

Many Aspects of Visual System Development Are Activity-Dependent

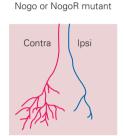

One well-studied example of activity-dependent development in the visual system is the sharpening of the topographic distribution of retinal ganglion cell axons onto their central targets, a topic we introduced in Chapter 54. Molecular cues such as ephrins guide

Figure 56–13 The critical period for monocular deprivation is extended in mice lacking Nogo signaling. The drawings show arborization patterns of thalamocortical axons carrying signals from contralateral and ipsilateral eyes to the binocular zone in visual cortex. Monocular deprivation during the critical period elicits a shift in ocular preference in neurons in the binocular zone in both wild type mice and mice mutant for Nogo or the Nogo receptor. After the normal critical period (at 45 days) monocular deprivation continues to elicit a marked shift in axonal input and ocular preference in mice mutant for Nogo-A or the Nogo receptor but not in wild type mice. The plot shows that elimination of Nogo signaling prevents closure of the critical period. (Adapted, with permission, from McGee et al. 2005.)

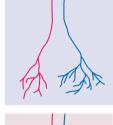

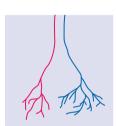

Binocular zone normal

Wild type

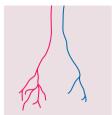

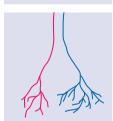

Monocular deprivation during the critical period (24 days)

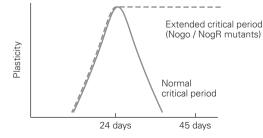

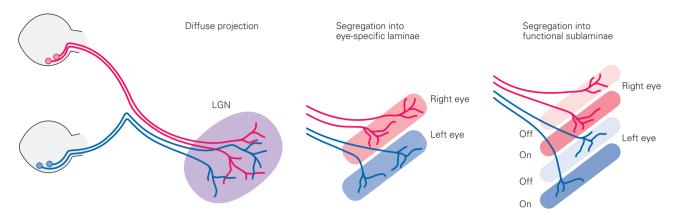

Figure 56–14 The terminals of retinal ganglion cells in the lateral geniculate nucleus become segregated during normal development. At early stages the terminals of axons from each eye intermingle. At later stages the inputs from the left

and right eyes segregate into separate layers of the nucleus. In some species axons from one eye even segregate into functionally specialized sublayers (on and off layers in ferrets). (Adapted, with permission, from Sanes and Yamagata 1999.)

axons to appropriate sites in the tectum, but they are not sufficient to form the refined visual map.

Histological and physiological studies have found that the map formed initially in the superior colliculus (the equivalent of the optic tectum of lower vertebrates) is coarse, and that individual retinal ganglion cell axons have large, overlapping arbors. These axonal arbors are later pruned to their mature size, resulting in a more restricted and precise field of termination. If retinal activity is inhibited, only the initial coarse map forms.

Is it the pattern of activity or activity itself that is important in visual map formation? Put another way, is activity simply "permissive" for refinement, or is it "instructive," determining exactly which axons win or lose the competition? Many experiments show that the latter idea is closer to the truth.

In one study the accuracy of the retinotectal map was assessed in fish raised in a tank illuminated only by brief flashes from a strobe light. A control group was raised in a normal laboratory environment. The total light intensity presented to the fish was similar under both conditions, but the resulting pattern was very different. In control fish the images fell haphazardly on various parts of the retina as the fish swam around their tanks. This input produces local synchronous activity of the sort generated by the waves of spontaneous activity described above—neighboring ganglion cells tend to fire together, but there is little correlation with the firing patterns of distant ganglion cells. In these fish the map becomes precise. In contrast, stroboscopic illumination synchronously activates nearly all of the ganglion cells, and as a consequence the retinotectal map remains coarse.

Presumably, the tectum determines which retinal axons are near neighbors by judging which ones fire in synchrony, much as activity patterns in the lateral geniculate nucleus or visual cortex determine which axons carry signals from the same eye. This information is then used to refine the topographic map, through mechanisms similar to those in the cortex. When all of the axons fire in synchrony, the tectum cannot determine which axons are neighbors; refinement fails, and the map remains coarse.

Auditory Maps Are Refined During a Critical Period

Activity-dependent refinement is not unique to the visual system. Activity is essential for shaping patterns of connectivity in most regions of the central nervous system. In the auditory system, for example, inputs form orderly tonotopic maps in the cochlear nucleus, the inferior colliculus, and the auditory cortex, such that neurons responding best to low frequencies lie at one edge of each structure, while neurons tuned to high frequencies are at the other. These maps underlie our sense of pitch. In addition, neurons vary in their sensitivity to sounds sensed by the contralateral and ipsilateral ears, and this discrepancy helps us determine the point in horizontal space from which a sound arises (see Chapter 31).

These auditory patterns are analogous to the retinotopic maps of the visual system. And, like their visual analogs, these auditory connections can be refined or modified by experience. Thus, although tonotopic maps can form in silence, exposure of an animal to "white noise" impairs refinement of the tuning curves

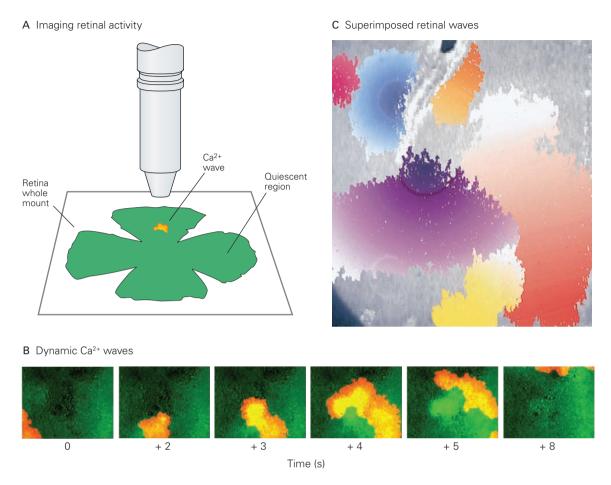

Figure 56–15 Correlated waves of neural activity in the developing retina.

A. Microscopic visualization of the activity of retinal ganglion neurons in a flat-mounted preparation of mammalian retina. Spontaneous waves of neural activity are visualized by monitoring Ca²⁺ transients (yellow domain) after loading of cells with dyes that change their fluorescent emission spectrum with changes in intracellular Ca²⁺ concentration.

B. These still images from a movie sequence show the propagation of one Ca²⁺ activity focus (yellow domain) across the

retina. Images were taken 1 second apart. Many cells within the activity focus are activated synchronously (Reproduced, with permission, from Blankenship et al. 2009).

C. Retinal activity waves recorded over time are superimposed in this image. Discrete waves are indicated in different colors; the origin of a wave is indicated by a darker hue. These waves originate in different retinal foci and spread in distinct, unpredictable directions. (Reproduced, with permission, from Meister et al. 1991.)

of neurons in the inferior colliculus, while exposure to specific frequencies enhances representation of those frequencies in the map.

Neural circuit reorganization not only optimizes processing of information in one sensory modality but also brings information of multiple sensory modalities into register. Studies on barn owls have provided insight into how auditory and visual maps are coordinated during a critical period. During the day owls use vision to localize their prey—mice or other small rodents—but at night they rely on auditory cues, and at dusk both sensory channels are used. The localization of sound must

be precise if owls are to succeed in finding prey, and it is intuitively obvious that the visual and auditory cues for the same location need to be consistent.

Auditory localization in owls, as in people, results in large part from computation of the temporal difference between a sound arriving at the two ears. This difference is only a few tens of microseconds, as expected from calculations based upon the speed of sound and the width of the head. Remarkably, the auditory system is sensitive to these extremely short interaural time differences (ITDs) and can calculate prey position from them (Figure 56–16). Moreover, many neurons in the

optic tectum with receptive fields centered on a particular location are also tuned to ITDs that correspond to sounds emitted from that same point in space. The registration is imprecise at early stages but becomes progressively more precise during early adolescence as a consequence of the animal's experience.

Crucial insight into how this registration occurs came from experiments in which prisms were mounted over the eyes of owls of different ages. The prisms shifted the retinal image horizontally so that the visual map in the tectum reflected a world systematically displaced from its "actual" orientation. This change abruptly disrupted the correspondence between visual and auditory receptive fields. Over the next several weeks, however, the ITD to which tectal neurons responded optimally, ie, their auditory receptive fields changed until the visual and auditory maps came back into register (Figure 56–17). Thus the visual map instructs the auditory map.

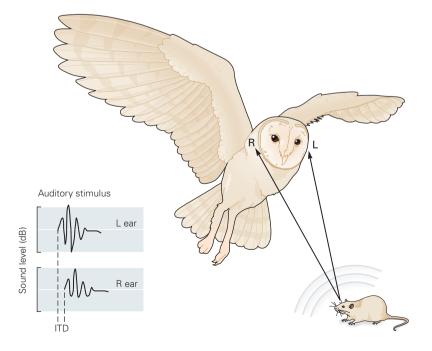

Further experiments showed that this reorganization resulted from rewiring of connections between two deeper auditory nuclei (Figure 56–18). When prism goggles were placed on young owls, changes in ITD tuning were fully adaptive, in that the animals compensated completely for the effects of the prisms. In contrast, goggles placed on mature owls (older than 7 months of age) had little effect. Thus reorganization of this auditory projection occurs optimally during a critical juvenile period.

Distinct Regions of the Brain Have Different Critical Periods of Development

Not all brain circuits are stabilized at the same time. Even within the visual cortex the critical periods for organization of inputs differ among layers. As an example, the neural connections in layer IVC of the visual cortex of the monkey are not affected by monocular deprivation by the time the animal is two months old. In contrast, connections in the upper and lower layers continue to be influenced by sensory experience (or lack of it) for almost the entire first year after birth. Critical periods for other features of the visual system, such as orientation tuning, occur at different developmental stages (Figure 56–19A).

The timing of critical periods also varies between brain regions (Figure 56–19B). The adverse consequences of sensory deprivation for the primary sensory regions of the brain are generally fully realized early in postnatal development. In contrast, social experience can affect the intracortical connections over a much longer period. These differences may explain why certain types of learning are optimal at particular stages of development. For example, certain cognitive capacities—language, music, and mathematics—usually must be acquired well before puberty if they are to develop at all. In addition, insults to the brain at specific early stages of postnatal life may selectively affect the development of certain perceptual abilities and behavior.

Figure 56–16 The barn owl uses interaural time differences to localize its prey. Sound waves generated by movements of a mouse are received by the owl's left and right ears. As the prey emits noise, the difference in the time of arrival of auditory stimuli at the two ears—the interaural time difference (ITD)—is used to calculate the precise position of the prey target. (Reproduced, with permission, from Knudsen 2002.)

Critical Periods Can Be Reopened in Adulthood

By definition critical periods are limited in time. However, it is now clear that they are less sharply defined than previously thought. Extending or reopening critical periods in adulthood could increase brain plasticity and make it possible to facilitate recovery from strokes and other insults that inactivate discrete regions of the nervous system.

Some of the best evidence for the view that critical periods can be extended comes from studies on matching of auditory and visual maps in owls. In initial experiments the realignment of auditory and visual maps following displacement of the visual field with prism goggles was largely restricted to an early sensitive period. However, three strategies dramatically enhance binaural tuning plasticity in adult owls.

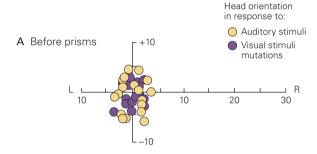

First, when adult owls that had worn goggles as adolescents are refitted with the goggles, the auditory map again shifts to align with the new visual map (Figure 56–20A). In contrast, in adult owls that had not worn the goggles as adolescents, the use of goggles has little effect on the organization of the auditory map. Thus the events of map rearrangement during the normal critical period must leave a neural trace that permits rearrangement later in life. In fact, in the owls that wore prisms in early life, axonal projections to auditory nuclei that were normally pruned were maintained, providing a structural basis for the reorganization in adulthood.

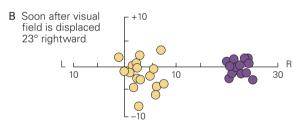

A second method for inducing late plasticity is to displace the retinal image in small steps by having the owl wear a series of prism spectacles of progressively increasing strength. Under these conditions adjustment

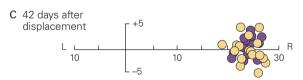

Figure 56–17 Reorganization of sensory maps in the optic tectum of owls after systematic displacement of the retinal image. The retinal image in adolescent owls can be displaced by prism goggles, which shift images from 5 to 30 degrees. (Modified, with permission, from Knudsen 2002.)

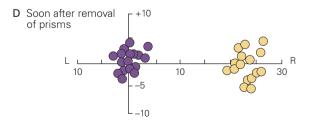

- **A.** Before application of the prisms the visual and auditory neural maps coincide.
- **B.** The prism goggles displace the retinal image by 23 degrees. Consequently, the neural and auditory maps are out of alignment.
- **C.** The two brain maps are once again congruent 42 days after prism application because the auditory map has shifted to realign with the visual map.
- **D.** Soon after the prisms are removed, the visual map reverts to its original position, but the auditory map remains in its shifted position.

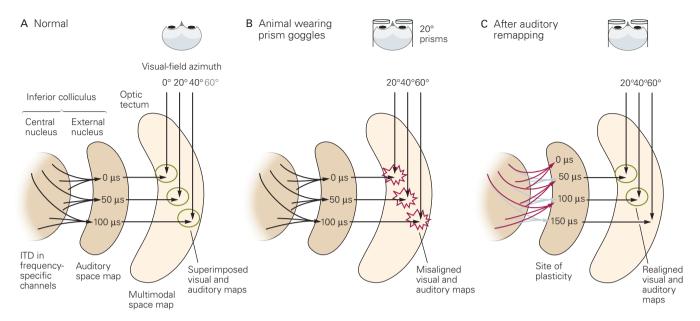

Figure 56–18 The effect of prism experience on information flow in the midbrain auditory localization pathway in the barn owl. (Modified, with permission, from Knudsen 2002.)

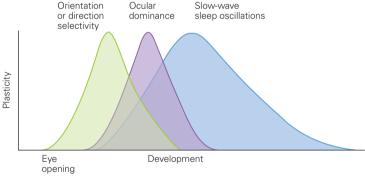

A. The auditory pathway in a normal owl. The interaural time difference (ITD) is measured and mapped in frequency-specific channels in the brain stem. This information ascends to the inferior colliculus, where a neural map of auditory space is

created. The map is conveyed to the optic tectum where it merges with a map of visual space.

- **B.** After an owl is fitted with prism goggles the visual and auditory space maps in the optic tectum become misaligned.
- C. After reorganization of auditory maps, the visual and auditory maps are once again in alignment.

B The effect of incremental change

C The effect of hunting

Figure 56–20 Specific behavioral regimes have different effects on the realignment of visual and auditory neural maps in the mature barn owl.

A. The remodeling of the auditory maps that results from wearing prism goggles for a brief period during adolescence leaves a neural trace that can be reactivated in the adult. When these birds are fitted with the goggles as adults, the auditory map is still able to realign with the visual map. (Reproduced, with permission, from Knudsen 2002.)

B. When an animal is fitted with a series of prisms, each of which produces a small displacement in the visual image, the

auditory map is successfully brought into alignment. The dotted line shows the extent of realignment if the animal is fitted with a 23 degree prism on day 0. (Reproduced, with permission, from Linkenhoker and Knudsen 2002.)

C. If an adult owl has the opportunity to hunt live prey while wearing prism goggles, auditory remapping occurs, perhaps because of enhanced motivation to sharpen perception. (Reproduced, with permission, from Bergan et al. 2005.)

of the auditory map is typically two- to threefold greater than the response to a single large displacement of the retinal image (Figure 56–20B).

The third technique is to allow owls to hunt live prey. In earlier experiments on plasticity in the optic tectum of owls, the animals were housed and fed under standard laboratory conditions. However, when adult prism-wearing owls are allowed to capture live mice under low light conditions for 10 weeks, they exhibit far greater plasticity than owls fed dead mice

(Figure 56–20C), albeit less than that exhibited by juvenile owls that did not hunt. So hunting increases the plasticity of binaural tuning in adult owls. This finding provides a dramatic demonstration that behavioral context affects the ability of the nervous system to reorganize. Whether this effect results from increased sensory information, attention, arousal, motivation, or reward needs to be resolved.

Recent data suggest that critical periods can also be extended or reopened in mammals. There have even

been reports that the best-studied critical period, the period for formation of ocular dominance columns, can be modified. Human amblyopia can be ameliorated in adulthood by training. In addition, new insights into the molecular mechanisms underlying critical periods in mice have suggested pharmacological strategies to extend or reopen critical periods. Encouraging results have already been obtained with drugs that alter inhibitory circuitry, destabilize perineuronal nets, or neutralize the growth inhibiting properties of myelin.

How can we reconcile the strong evidence for critical periods with the newer evidence for reorganization of circuitry in adults? The plasticity of critical periods can be distinguished from plasticity in adulthood by its magnitude and by the ease with which it is triggered. These differences result from two factors. First, from early postnatal life into adolescence the molecular environment in the brain is conducive to axonal growth, and cellular mechanisms are optimal for promoting the formation, strengthening, weakening, and elimination of synapses. Under these conditions circuits can undergo fundamental changes in their architecture and biochemistry in response to the animal's experience. Conversely, in mature circuits molecular and structural elements promote stability and impede plasticity.

Second, in a developing circuit no particular pattern of connectivity is firmly entrenched, so there is less to overcome. The connections specified by genetic determinants are less precise and the connections themselves are relatively weak. The patterns of neural activity that are stimulated by experience sharpen and even realign these patterns of connectivity. Once a pattern of connectivity becomes established, strong activation of the established circuit impedes the development of alternative wiring. This difference may help explain the special circumstances needed to trigger plasticity in adulthood. Circuits can be altered by passive exposure of animals to unusual environments during the critical period, whereas adult plasticity may require that the animal pay attention to the stimulus. In sum, experience during critical periods has a potent effect on circuits because the cellular and molecular conditions are optimal for plasticity and because the instructed pattern of connectivity does not have to compete with a long-existing pattern.

An Overall View

Connections among neurons in the mammalian brain arise from two fundamentally different developmental programs: molecular guidance cues and patterned neural activity. Molecular cues guide axons to target regions and initiate the formation of synaptic connections. Once synaptic contact is established, however, continued development depends on the coordination of neural activity between pre- and postsynaptic neurons.

In many instances activity is stimulated by sensory experience, allowing a circuit to refine itself to suit a particular environment. This remarkable ability allows the nervous system to be, in essence, individualized so that it performs optimally. Conversely, it would be maladaptive to allow experience to trigger large-scale reorganization of the nervous system in adults, once behaviors have been established and skills learned. Perhaps for this reason, refinement of neural circuits in response to environmental conditions is largely restricted to critical periods in early development.

Activity-dependent reorganization has been studied in greatest detail in the visual system, particularly in the development of a coordinated binocular view of the world. If afferent fibers carrying input from the same region of the retina of one eye converge on a common cortical neuron, they have an advantage. Their synchronous firing strengthens the synapses of all cooperating fibers, while the synapses of the noncooperating fibers from the other eye decline.

These functional changes lead to local structural changes, for example in dendritic spines, and eventually to large-scale structural changes, with some axon terminals sprouting new synaptic contacts and others withdrawing entirely. As a consequence, overlap of inputs from the two eyes is eliminated and the inputs from the two eyes become segregated into alternating columns in the cortex. If vision is lost in one eye, the cortex reorganizes to devote most of its space to the open eye: Responsiveness to the deprived eye decreases and columns of cells receiving input from the deprived eye shrink, while responsiveness to the open eye increases and its columns expand. One can think of this reorganization as adaptive in that it ensures that as much of the cortex as possible ends up being used.

Studies of monocular deprivation have also provided insight into mechanisms that restrict plasticity in particular circuits to critical periods. A proper balance of excitation and inhibition may be necessary to initiate the critical period. During this period the segregation of afferent fibers and establishment of ocular dominance columns is affected dramatically by changing the balance of activity in the fibers from the two eyes. After the critical period existing connections stabilize and are much less susceptible to such modification. Myelination of axons and formation of matrix-rich nets around interneurons contribute to the stabilization. Studies of

the development of ocular dominance columns suggest how other, more complex sensory experiences early in development might change the circuitry and structure of the growing brain.

Because of the enduring nature of neural changes early in life, critical periods are times of both great opportunity and great vulnerability. If the environment to which an animal is exposed during a critical period is representative of the environment it will experience as an adult, plasticity shapes the connectivity of a circuit to make optimal use of cortical real estate and process information optimally. However, maladaptive stimulation during this period can lead to lifelong defects. Social deprivation in early childhood, for example, has lasting effects on social behavior. Some behavioral disorders such as autism may also result in part from aberrant or defective circuit maturation during critical periods.

It has long been clear that reopening of critical periods could, if properly controlled, have numerous benefits. Therapies could be designed to reorganize and retrain the brain to compensate for losses incurred by injuries and disease. Maladaptive reorganization in childhood could be remedied. It might even be possible for adults to learn new skills with some of the effortless efficiency that children exhibit during their critical periods. These possibilities remain science fiction, but it is heartening that recent studies have begun to reveal ways of extending or reopening critical periods in animals, by training regimens or in a few cases pharmacological intervention.

An Overall View

OR MUCH OF ITS HISTORY NEUROLOGY has been a discipline of outstanding diagnostic rigor but little therapeutic efficacy. Simply put, neurologists

have been renowned for their ability to localize lesions with great precision but until recently have had little to offer in terms of treatment. During the past decade this situation has begun to change.

Advances in our understanding of the structure, function, and chemistry of the brain's neurons, glial cells, and synapses have led to new ideas for treatment. Many of these are now in clinical trials and some are already available to patients. Developmental neuroscience is emerging as a major contributor to this sea change for three main reasons. First, efforts to preserve or replace neurons lost to damage or disease rely on recent advances in our understanding of the mechanisms that control the generation and death of nerve cells (see Chapters 52 and 53). Second, efforts to improve the regeneration of neural pathways following injury draw heavily on what we have learned about the growth of axons and the formation of synapses (see Chapters 54 and 55). Third, there is increasing evidence that some devastating brain disorders, such as autism and schizophrenia, are the result of disturbances in the formation of neural circuits in embryonic or early postnatal life. Accordingly, studies of normal development may provide an essential foundation for discovering precisely what has gone wrong in disease.

In this chapter we focus on the first two of these issues: How neuroscientists hope to augment the limited ability of neurons to recover normal function. We shall begin by describing how axons degenerate following the separation of the axon and its terminals from the cell body. The regeneration of severed axons is robust in the peripheral nervous system of mammals and in the central nervous system of lower vertebrates, but very poor in the central nervous system of mammals. Many

investigators have sought the reasons for these differences in the hope that understanding them will lead to methods for augmenting recovery of the human brain and spinal cord following injury. Indeed, we shall see that several differences in regenerative capacity of mammalian neurons have been discovered, each of which has opened promising new approaches to therapy.

Next we shall consider an even more dire consequence of neural injury: the death of neurons. The inability of the adult brain to form new neurons has been a central dogma of neuroscience since the pioneering neuroanatomist Santiago Ramón y Cajal asserted that in the injured central nervous system, "Everything may die, nothing may be regenerated." This pessimistic view dominated neurology for most of the last century despite the fact that Ramón y Cajal added, "It is for the science of the future to change, if possible, this harsh decree." Remarkably, in the past few decades evidence has accumulated that neurogenesis does occur in certain regions of the adult mammalian brain. This discovery has helped accelerate the pace of research on ways to stimulate neurogenesis and to replace neurons following injury. Although this work is preliminary, and in some respects controversial, it

now seems possible that in the future neuroscientists will be able to reverse Cajal's "harsh decree."

Damage to Axons Affects Neurons and Neighboring Cells

Because neurons have very long axons and cell bodies of modest size, most injuries to the central or peripheral nervous system involve damage to axons. Transection of the axon, either by cutting or by crushing, is called *axotomy*, and its consequences are numerous.

Axon Degeneration Is an Active Process

Axotomy divides the axon in two: a proximal segment that remains attached to the cell body and a distal segment that has lost this crucial attachment. Axotomy dooms the distal segment of the axon. Synaptic transmission soon fails at severed nerve terminals. After a delay, physical degeneration of the axon occurs and once it begins its progression is relatively rapid and inevitably proceeds to completion (Figure 57–1). Within the distal segment the neuronal membrane breaks down, the cytoskeleton is disassembled, and

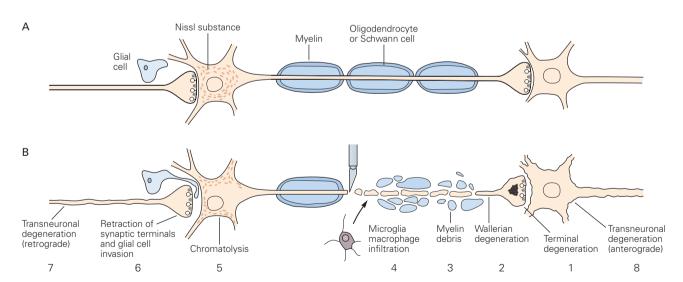

Figure 57–1 Axotomy affects the injured neuron and its synaptic partners.

A. A normal neuron with an intact functional axon wrapped by myelinating cells contacts a postsynaptic neuron. The neuron's cell body is itself a postsynaptic target.

B. After axotomy the nerve terminals of the injured neuron begin to degenerate (1). The distal axonal stump separates from the parental cell body, becomes irregular, and undergoes

Wallerian degeneration (2). Myelin begins to fragment (3) and the lesion site is invaded by phagocytic cells (4). The cell body of the damaged neuron undergoes chromatolysis: The cell body swells and the nucleus moves to an eccentric position (5). Synaptic terminals that contact the damaged neuron withdraw and the synaptic site is invaded by glial cell processes (6). The injured neuron's inputs (7) and targets (8) can atrophy and degenerate.

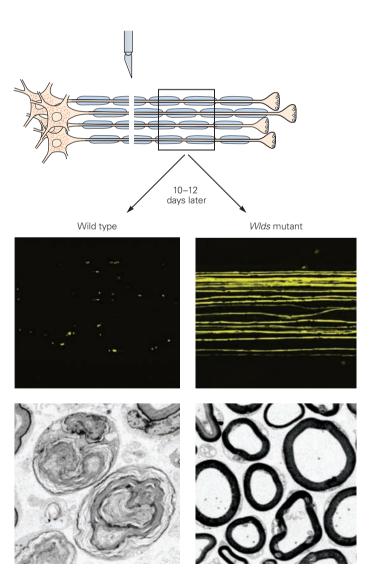

cytoskeletal components are degraded. This degenerative response is the first step in an elaborate constellation of changes that were initially described in 1850 by Augustus Waller, changes that are now called *Wallerian degeneration*.

The degeneration of transected axons was long thought to be a passive process, the consequence of separation from the neuronal cell body, within which most of the cell's proteins are synthesized. Lacking a source of new protein, the distal stump would, in essence, wither away. But the discovery and analysis in mice of a spontaneously occurring mutant called *Wlds* (Wallerian degeneration slow) challenged this view (Figure 57–2). In the *Wlds* mutant the distal stumps of peripheral nerves persist for several weeks after transection, about 10-fold longer than in normal mice.

The *Wlds* mutation results in the fusion of two normal proteins into a novel protein. One of the contributing proteins is normally involved in biosynthesis of a metabolic cofactor, nicotinamide adenine dinucleotide (NADH), and the other is normally involved in ubiquitination, the process that covalently modifies proteins for degradation.

It remains unclear how the presence of the *Wlds* fusion protein slows degeneration so dramatically, but its discovery has been important in several ways. First, the very fact that degeneration *can* be slowed proves that it is not a passive consequence of separation from the cell body, but is rather an actively regulated response. Second, the nature of the *Wlds* protein has already given us clues about the nature of the active process that drives Wallerian degeneration.

Figure 57–2 Axonal degeneration is delayed in *Wlds* mutant mice. After sectioning of a peripheral nerve in wild type animals, axons in the distal stump degenerate rapidly, as shown by disrupted axonal fragments (yellow) and the lack of myelinated axonal profiles at the electron micrographic level. In *Wlds* mutant mice the distal portion of severed axons persists for a long time. (Top two confocal micrographs reproduced, with permission, from Beirowski et al. 2004. Bottom two electron micrographs reproduced, with permission, from Michael Coleman.)

Third, and perhaps most importantly, insight into how the Wlds fusion protein acts may be useful in devising treatments for neurological disorders in which axonal degeneration is prominent. A fatal disease of motor neurons, amyotrophic lateral sclerosis, falls into this category. Other possibilities include some forms of spinal muscular atrophy, Parkinson disease, and even Alzheimer disease. Axon degeneration that occurs in these diseases, as well as after metabolic, toxic, or inflammatory insults, resembles the degeneration that follows acute trauma and may be regulated in similar ways. Expression of the Wlds fusion protein significantly delays axonal loss and can even extend the life span of certain mouse models of motor neuron disease. Thus, while methods for saving transected distal axons are unlikely to be useful clinically for treating patients who have suffered traumatic injury, the same techniques could be useful in treating neurodegenerative diseases.

We return now to the injured axon itself. Even though the proximal portion of the axon remains attached to the cell body, it too suffers. And in some cases the neuron itself dies by apoptosis, probably because axotomy isolates the neuronal cell body from its supply of target-derived trophic factors. Even when this does not occur, the cell body often undergoes a series of cellular and biochemical changes called the *chromatolytic reaction:* The cell body swells, the nucleus moves to an eccentric position, and the rough endoplasmic reticulum becomes fragmented (Figure 57–1B). Chromatolysis is accompanied by other metabolic changes, including an increase in protein and RNA synthesis as well as a change in the pattern of genes that the neuron expresses. These changes are reversible if regeneration is successful.

Axotomy Leads to Reactive Responses in Nearby Cells

Axotomy sets in motion a cascade of responses in numerous types of neighboring cells. Among the most important responses are those of the glial cells that ensheath the distal nerve segment. The myelin sheath becomes fragmented and eventually removed.

This process is rapid in the peripheral nervous system, where the myelin-producing Schwann cells break the myelin into small fragments and engulf it. Schwann cells, which then divide, secrete factors that recruit macrophages from the blood stream. The macrophages in turn assist in the disposal of debris. Schwann cells also produce growth factors that promote axon regeneration, a point to which we will return later.

In contrast, in the central nervous system the myelin-forming oligodendrocytes have little or no ability

to dispose of myelin, and the blood-brain barrier prevents the entry of macrophages, so removal of debris depends on a limited quantity of resident macrophages called *microglia*. These differences in cellular properties explain the observation that Wallerian degeneration proceeds to completion much more slowly in the central nervous system.

Axotomy also affects postsynaptic neurons. When axotomy disrupts the major inputs to a cell—as happens in denervated muscle, or to neurons in the lateral geniculate when the optic nerve is cut—the consequences are severe. Usually the target atrophies and sometimes dies. When targets are only partially denervated, their responses are more limited. In addition, axotomy affects presynaptic neurons. In many instances synaptic terminals withdraw from the cell body or dendrites of chromatolytic neurons and are replaced by the processes of glial cells—Schwann cells in the periphery and microglia or astrocytes in the central nervous system. This process, called *synaptic stripping*, depresses synaptic activity and can impair functional recovery.

Although the mechanism of synaptic stripping remains unclear, two possibilities have been suggested. One is that postsynaptic injury causes axon terminals to lose their adhesiveness to synaptic sites so that they are subsequently wrapped by glia. The other is that glia initiate the process of synaptic stripping in response to factors released from the injured neuron or to changes in its cell surface. Whatever the trigger, the activation of microglia and astrocytes by axotomy clearly contributes to the stripping process. In addition, biochemically altered astrocytes, called reactive astrocytes, contribute to formation of a *glial scar* near sites of injury.

As a result of these transsynaptic effects, neuronal degeneration can propagate through a circuit in both anterograde and retrograde directions. For example, a denervated neuron that becomes severely atrophic can fail to activate its target, which in turn becomes atrophic. Likewise, when synaptic stripping prevents an afferent neuron from obtaining sufficient sustenance from its target cell, the afferent neuron's inputs are placed at risk. Such chain reactions help to explain how injury to one site in the central nervous system eventually affects regions far from the source of the injury.

Central Axons Regenerate Poorly After Injury

Central and peripheral nerves differ substantially in their ability to regenerate after injury. Peripheral nerves can often be repaired following injury. Although the

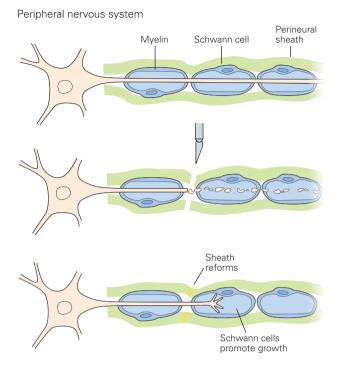

Figure 57–3 Axons in the periphery regenerate better than those in the central nervous system. After sectioning of a peripheral nerve, the perineural sheath reforms rapidly and Schwann cells in the distal stump promote axonal growth by producing trophic and attractant factors and expressing high

Oligodendrocyte

Myelin

Glial scar

Central nervous system

levels of adhesive proteins. After sectioning of axonal tracts in the central nervous system, the distal segment disintegrates and myelin fragments. In addition, reactive astrocytes and macrophages are attracted to the lesion site. This complex cellular milieu, termed a *glial scar*, inhibits axonal regeneration.

Macrophage

infiltration

astrocyte

invasion

distal segments of axons degenerate, connective tissue elements surrounding the distal stump generally survive. Axonal sprouts grow from the proximal stump, enter the distal stump, and grow along the nerve toward its targets (Figure 57–3). The mechanisms that drive this process are related to those that guide embryonic axons. Chemotropic factors secreted by Schwann cells attract axons to the distal stump, adhesive molecules within the distal stump promote axon growth along cell membranes and extracellular matrices, and inhibitory molecules in the perineural sheath prevent regenerating axons from going astray.

Once regenerated peripheral axons reach their targets they are able to form new functional nerve endings. Motor axons form new neuromuscular junctions; autonomic axons successfully reinnervate glands, blood vessels, and viscera; and sensory axons reinnervate muscle spindles. Finally, those axons that lost their myelin sheaths are remyelinated, and chromatolytic cell bodies regain their original appearance. Thus in all three divisions of the peripheral nervous system—

motor, sensory, and autonomic—the effects of axotomy are reversible. This is not to imply that peripheral regeneration is perfect. In the motor system recovery of strength may be substantial, but recovery of fine movements is usually impaired. Some motor axons form synapses on inappropriate muscle fibers, some peripheral axons never find their targets, and some neurons die. Nevertheless, the regenerative capacities in the peripheral nervous system are impressive.

In contrast, in the central nervous system regeneration after injury is poor (Figure 57–3). The proximal stumps of damaged axons can form short sprouts, but these soon stall and form swollen endings called "retraction bulbs" that fail to progress. Long-distance regeneration is rare. The longstanding failure of central regeneration has led to the pessimistic view that injuries to the brain and spinal cord are largely irreversible, and that therapy must be restricted to rehabilitative measures.

For some time neurobiologists have been seeking the reasons why regenerative capacity in the central and peripheral nervous systems differs so dramatically. The goal of this work is to identify the crucial barriers to regeneration so that they can be overcome. These studies have begun to bear fruit, and there is now cautious optimism that the injured human brain and spinal cord have a regenerative capacity that can eventually be exploited.

Before discussing these new developments it is helpful to consider the problem of neural regeneration in a broader biological context. Is it the ability of peripheral axons to regenerate that is unusual, or the inability of central axons to do so? It is in fact the latter. Obviously, central axons grow well during development. More surprisingly, axons in immature mammals can also regenerate following transection in the brain or spinal cord. Moreover, regeneration is robust in the central nervous systems of lower vertebrates such as fish and frogs, as exemplified by the studies of Roger Sperry on restoration of vision following damage to the optic nerve (see Chapter 54).

So why have mature mammals lost this seemingly important capacity for repair? The answer may lie in what the mammalian brain can do peerlessly, which is to remodel its basic wiring diagram in accordance with experience during critical periods in early postnatal life, so that each individual's brain is optimized to deal with the changes and challenges of internal and external worlds (see Chapter 56). But once remodeling has occurred, it must be stabilized. It is obviously useful to reassign cortical space to one eye if the other is blinded in childhood, but we would not want our cortical connections similarly rearranged in response to a brief period of unusual illumination or darkness. Maintaining constancy in the face of small perturbations in connectivity may therefore have the unavoidable consequence of limiting the ability of central connections to regenerate in response to injury. In this view our limited regenerative capacity is the Faustian biological bargain we have made for the possession of many precisely wired circuits that underlie our superior intellectual powers.

Therapeutic Interventions May Promote Regeneration of Injured Central Neurons

In seeking reasons for the poor regeneration of central axons, one critical question is whether the poor recovery reflects an inability of neurons themselves to grow or an inability of the environment to support axonal growth. This issue was addressed by Albert Aguayo and his colleagues in the early 1980s. They inserted segments of a central nerve trunk into a peripheral

nerve graft, and segments of a peripheral nerve into the brain or spinal cord, to find out how the translocated axons would respond.

Aguayo found that the axons in the translocated segments promptly degenerated, leaving "distal stumps" containing glia, support cells, and extracellular matrix. The results were striking. Spinal axons that regenerated poorly following spinal cord injury grew several centimeters when inserted into a peripheral nerve (Figure 57–4). Conversely, peripheral axons regenerated well through their own distal nerve trunk, but fared poorly when paired with a severed optic nerve (Figure 57–5).

Aguayo extended these studies to show that axons from multiple regions, including the retinal ganglion, olfactory bulb, brain stem, and mesencephalon, could each regenerate long distances if provided with a suitable environment. As we will see later, it turns out that regrowth of central axons is intrinsically limited. Nevertheless, these pioneering experiments focused attention on components of the central environment that inhibit regenerative ability and motivated an intensive search for the molecular culprits.

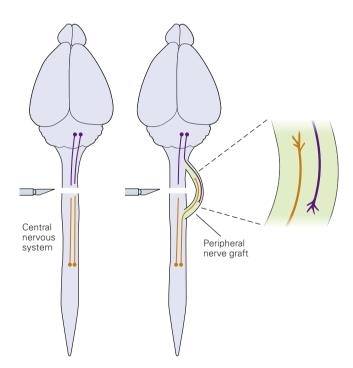

Figure 57–4 A transplanted peripheral nerve provides a favorable environment for the regeneration of central axons. Left: After sectioning of the spinal cord, ascending and descending axons fail to cross the lesion site. Right: Insertion of a bridging peripheral nerve graft that bypasses the lesion site promotes regeneration of both ascending and descending axons. (Adapted, with permission, from Aguayo 1981.)

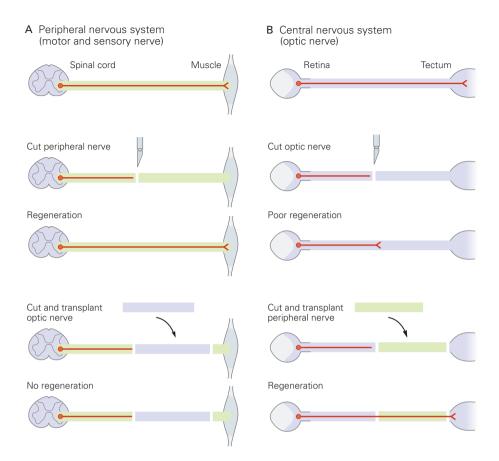

Figure 57–5 Peripheral and central nerves differ in their ability to support axonal regeneration.

A. In the peripheral nervous system severed axons regrow past the site of injury. Insertion of a segment of optic nerve into a peripheral nerve suppresses the ability of the peripheral nerve to regenerate. **B.** In the central nervous system severed axons typically fail to regrow past the site of injury. Insertion of a section of peripheral nerve into a central nerve tract promotes regeneration.

Environmental Factors Support the Regeneration of Injured Axons

In probing the differences between peripheral and central growth environments, initial searches were influenced by the results of experiments performed by Ramón y Cajal's student Jorge Tello-Muñoz nearly a century before Aguayo's studies. Tello transplanted segments of peripheral nerves into the brains of experimental animals and found that injured central axons grew toward the implants, whereas they barely grew when implants were not available.

This result implied that peripheral cells provide growth-promoting factors to the injured areas; factors normally absent from the brain. Ramón y Cajal reasoned that central nerve pathways lacked "substances able to sustain and invigorate the indolent and scanty growth" similar to those provided by peripheral pathways. Numerous studies over the succeeding century identified constituents of peripheral nerves that are potent promoters of neurite outgrowth. These include components of Schwann cell basal laminae such as laminin, and cell adhesion molecules of the immunoglobulin superfamily. In addition, cells in denervated distal nerve stumps begin to produce neurotrophins and other trophic molecules. Together these molecules nourish neurons and guide growing axons in the embryonic nervous system, so it makes sense that they also promote the regrowth of axons. By contrast, central neuronal tissue is a poor source of these molecules, containing little laminin and low levels of trophic molecules. Thus in the embryo both central and peripheral nervous systems provide environments that promote axon outgrowth. But only the peripheral environment retains this capacity in adulthood, or is able to regain it effectively following injury.

The practical implications of this view are that supplementing the central environment with growth-promoting molecules might improve regeneration. To this end investigators have infused neurotrophins into areas of injury or inserted conduits rich in extracellular matrix molecules such as laminin. In some attempts Schwann cells themselves, or cells engineered to secrete trophic factors, have been grafted into sites of injury. In many of these cases injured axons grow slightly more extensively than they do under control conditions. Yet regeneration remains limited, with axons generally failing to extend long distances. More important, functional recovery is minimal.

What accounts for such disappointingly limited regeneration? One limitation appears to be the existence of inhibitory signaling pathways that block the growth-promoting activity of cytokine factors. In the optic nerve, for example, the poor regeneration of the axons of retinal ganglion neurons is accounted for in part by the state of activation of a cytokine signaling pathway. The axonal growth-promoting effects of cytokines such as ciliary neurotrophic factors (CNTFs) involve activation of a receptor GP130, and GP130 signaling is counteracted by the activity of a suppressor of cytokine signaling called SOCS3. Thus deletion of the SOCS3 gene in mice augments the ability of CNTF to promote regeneration of retinal ganglion cell axons in the optic nerve (Figure 57–6).

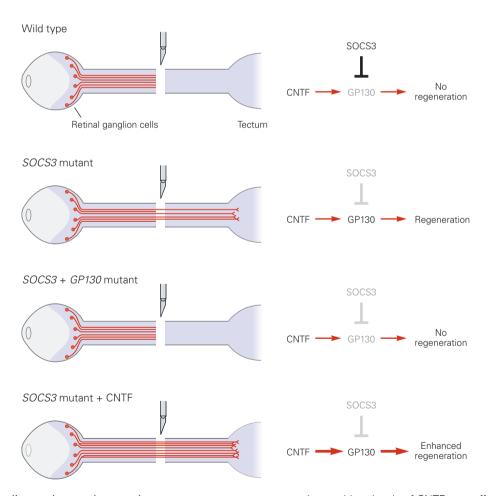

Figure 57–6 Signaling pathways that regulate axon regeneration in the optic nerve. The regeneration of retinal ganglion cell axons in the optic nerve is normally constrained by neuronal expression of the gene for SOCS3, which blocks the ability of ciliary neurotrophic factor (**CNTF**) to bind its receptor GP130 and thus blocks CNTF from promoting regeneration. In *SOCS3*

mutant mice, ambient levels of CNTF are sufficient to improve optic nerve regeneration. Elimination of GP130 as well as SOCS3 blocks the capacity for regeneration. Addition of extra CNTF enhances the capacity for regeneration in *SOCS3* mutant mice. (Adapted, with permission, from Smith et al. 2009.)

Components of Myelin Inhibit Neurite Outgrowth

Fragments of central myelin are potent inhibitors of neurite outgrowth. Sprouting of spinal axon collaterals following injury is enhanced in rats treated to prevent myelin formation in the spinal cord (Figure 57–7). These findings implied that although both central and peripheral environments might contain a supply of growth-promoting elements, central nerves also contain inhibitory components. That myelin inhibits neurite growth may seem peculiar, but in fact myelination normally occurs postnatally, after axon extension is largely complete.

Searches for the inhibitory components of central myelin turned up an embarrassment of riches. Several classes of molecules found at higher levels in central myelin compared to peripheral myelin are able to inhibit neurite outgrowth when presented to cultured neurons. The first to be discovered was identified when an antibody generated against myelin proteins proved to be capable of partially neutralizing myelin's ability to inhibit neurite outgrowth. Use of this antibody to isolate the corresponding antigen yielded the protein now called Nogo. Two other proteins, myelin-associated glycoprotein (MAG) and oligodendrocytemyelin glycoprotein (OMgp), initially isolated as major

components of myelin, have been found to inhibit the growth of some neuronal types.

Intriguingly, Nogo, MAG, and OMgp each bind to common membrane receptors, NogoR and PirB (Figure 57–8). In mutant mice lacking PirB, regeneration of severed corticospinal axons is enhanced; the extent of axonal regeneration in mice lacking NogoR or its three ligands is uncertain. Identifying physiologically relevant constraints on regeneration may be complicated by the presence of still undiscovered inhibitors. But if many inhibitory components trigger the same intracellular signaling pathway, then interference with that pathway might neutralize the impact of many inhibitors in one fell swoop.

Injury-Induced Scarring Hinders Axonal Regeneration

Myelin debris is not the only source of growthinhibiting material in the injured brain or spinal cord. As noted earlier, astrocytes become activated and proliferate following injury, acquiring features of reactive astrocytes that generate scar tissue at sites of injury. Scarring is an adaptive response that helps to limit the size of the injury, to reestablish the blood-brain barrier, and to reduce inflammation.

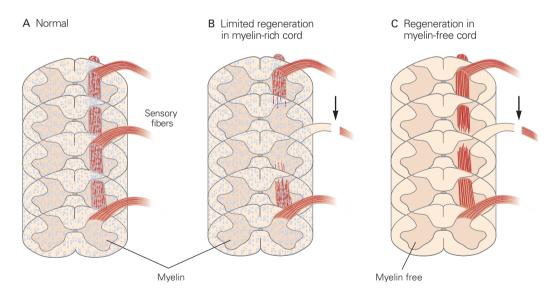

Figure 57–7 Myelin inhibits regeneration of central axons. (Adapted, with permission, from Schwegler, Schwab, and Kapfhammer 1995.)

A. Sensory fibers normally extend rostrally in a myelin-rich spinal cord.

B. Right dorsal root fibers were sectioned in 2-week-old normal rats. Regeneration of the fibers was assessed

histochemically 20 days later. The central branches of the sectioned axons degenerated, leaving a portion of the spinal cord denervated. Little regeneration occurred in the myelin-rich cord.

C. Some littermates received local x-irradiation to block myelination. In these animals sensory fibers that entered the cord through neighboring uninjured roots sprouted new collaterals following denervation.

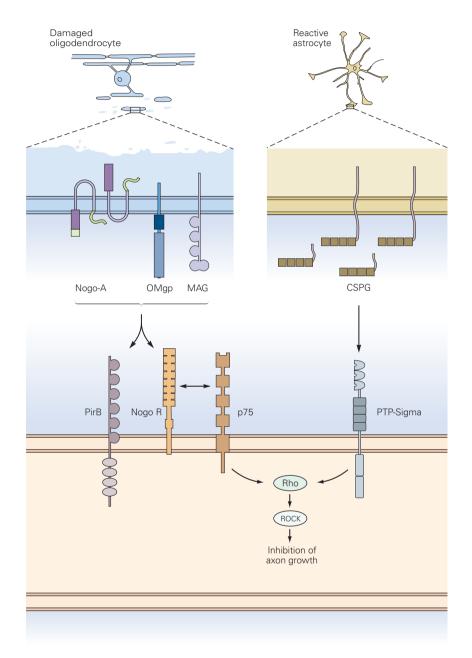

Figure 57–8 Myelin and glial scar components that inhibit regeneration of central axons. *Left*: Myelin contains the proteins Nogo-A, oligodendrocyte-myelin glycoprotein (**OMgp**), and myelin-associated glycoprotein (**MAG**). All three proteins are exposed when myelin breaks down. They can bind a receptor protein Nogo R, which can associate with the neurotrophin receptor p75, as well as an immunoglobulin-like receptor

protein PirB. Inactivation of PirB results in a modest enhancement of corticospinal axon regeneration. *Right*: Chondroitin sulphate proteoglycans (**CSPG**) are major components of the glial scar and are thought to suppress axon regeneration through interaction with the receptor tyrosine phosphatase PTP-sigma, which activates intracellular mediators such as Rho and ROCK. (Adapted, with permission, from Yiu et al. 2006.)

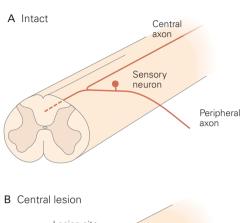

But the scar itself hinders regeneration in two ways: through mechanical interference with axon growth and through growth-inhibiting effects of proteins produced by cells within the scar. Chief among these inhibitors are a class of chondroitin sulfate proteoglycans (CSPG) that are produced in abundance by reactive astrocytes and directly inhibit axon extension by interaction with tyrosine phosphatase receptors on axons (Figure 57-8). Attention has therefore focused on ways of dissolving the glial scar by infusion of an enzyme called chondroitinase, which breaks down the sugar chains on CSPG. This treatment promotes axon regeneration and functional recovery in animals. Drugs that reduce inflammation and decrease scarring, notably prednisolone, are also beneficial if administered shortly after injury, before the scar forms.

An Intrinsic Growth Program Promotes Regeneration

So far we have emphasized differences between the local environments of peripheral and central axons. However, environmental differences cannot completely account for the poor regeneration of central axons. Even though they can regenerate in peripheral nerves, central axons grow much less well than peripheral axons when navigating the same path. Thus adult central axons may be less capable than peripheral axons of regeneration.

In support of this idea, experiments in tissue culture have shown that the growth potential of central neurons decreases with age, whereas mature peripheral neurons extend axons robustly in a favorable environment. One potential explanation for this difference is variation in the expression of proteins thought to be critical for optimal axon elongation, such as the 43 kDa growth-associated protein or GAP-43. This protein is expressed at high levels in embryonic central and peripheral neurons. In peripheral neurons the level remains high in maturity and increases even more following axotomy, whereas in central neurons its expression decreases as development proceeds.

Is this reduced ability of central axons to regenerate irreversible? Hope for reversibility is provided by studies involving "conditioning lesions." Recall that primary sensory neurons in dorsal root ganglia have a bifurcated axon, with a peripheral branch that extends to skin, muscle, or other targets, and a central branch that enters the spinal cord. The peripheral branch regenerates well following injury, whereas the central branch regenerates poorly. However, the central branch will regenerate successfully if the peripheral branch is damaged several days before the central branch is damaged (Figure 57–9). Somehow prior injury or conditioning lesion activates an axonal growth program.

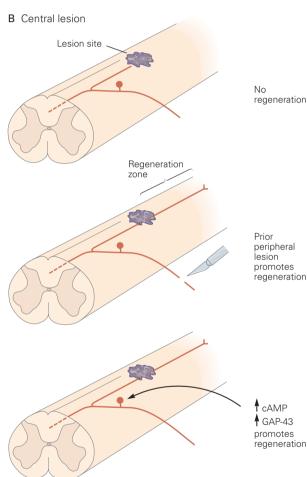

Figure 57–9 A conditioning lesion promotes regeneration of the central branch of a primary sensory neuron axon. After lesions of the spinal cord there is little regeneration of the central branch beyond the injury site. However, if the peripheral branch of the axon is sectioned before the central branch is damaged, the latter will grow beyond the lesion site. The impact of such a "conditioning lesion" can be mimicked by elevating levels of cyclic adenosine monophosphate (cAMP) or of the growth-associated protein GAP-43 in the peripheral branch.

One component of the growth program responsible for regeneration of the central branch appears to be cyclic adenosine monophosphate (cAMP). This second-messenger molecule activates enzymes that in turn promote neurite outgrowth. Levels of cAMP are high when neurons initially form circuits; they decline postnatally in central but not peripheral neurons. In some instances increased supplies of cAMP or proteins normally activated by cAMP can promote regeneration of central axons following injury. Accordingly, drugs that increase cAMP levels, or that activate targets of cAMP, are being actively considered as therapeutic agents to be administered following spinal cord injury. In addition, expression of GAP-43 can promote the regeneration of sensory axons past the site of a spinal cord lesion.

Formation of New Connections by Intact Axons Can Lead to Functional Recovery

So far we have discussed interventions designed to enhance the limited regenerative capacity of injured central axons. An alternative strategy focuses on the significant, although incomplete, functional recovery that can occur following injury even without appreciable regeneration of cut axons. If the basis for this limited recovery of function can be understood, it may be possible to enhance regeneration and function.

A rearrangement of existing connections in response to injury may contribute to recovery of function. We have learned that axotomy leads to changes in both the inputs to and the targets of the injured neuron.

Although many of these changes are detrimental to function, some are beneficial. In particular, the central nervous system can, following injury, spontaneously undergo adaptive reorganization that helps it regain function. For example, after transection of the descending corticospinal pathway, which occurs with many traumatic injuries of the spinal cord, the cortex can no longer transmit commands to motor neurons below the site of the lesion. Over several weeks, however, intact corticospinal axons rostral to the lesion begin to sprout new terminal branches and form synapses on spinal interneurons whose axons extend around the lesion, thereby forming an intraspinal detour that contributes to limited recovery of function (Figure 57–10).

Similar instances of functional reorganization have been demonstrated in the motor cortex and brain stem. These compensatory responses attest to the latent plasticity of the nervous system. The ability of the nervous system to rewire itself is most vigorous during the critical periods of early postnatal life (see Chapter 56) but can also be reawakened by traumatic events in adulthood.

How can the nervous system's rewiring ability be improved? It is possible that some of the beneficial effects of grafts in experimental animals reflect reorganization of intact axons rather than regeneration of transected axons. As the nervous system's plasticity becomes better understood, therapeutic strategies that promote specific changes in circuitry may become possible. Perhaps most promising is an approach in which cellular or molecular interventions that promote growth are combined with behavioral therapies that result in circuit rewiring.

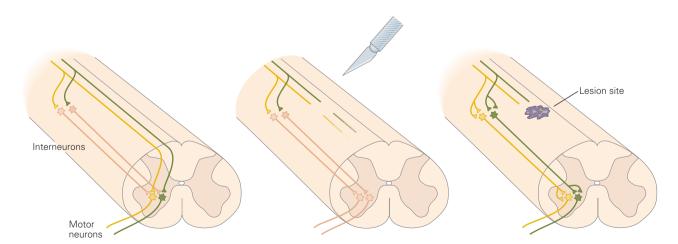

Figure 57–10 Function can be recovered after spinal cord injury through reorganization of spinal circuits. Severed corticospinal axons can reestablish connections with motor neurons by sprouting axon collaterals that innervate

propriospinal interneurons whose axons bypass the lesion and contact motor neurons located caudal to the lesion site. (Adapted, with permission, from Bareyre et al. 2004.)

Neurons in the Injured Brain Die but New Ones Can Be Born

The failure to grow a new axon is by no means the worst fate that can befall an injured neuron. For many neurons axotomy leads to the death of the cell. Efforts to improve recovery following injury therefore need to consider neuronal survival as well as axonal regrowth. Since neuronal death is a frequent consequence of severe neural insults, such as stroke and neurodegenerative disease, improved ways of retaining or replacing neurons would have broad utility.

The loss of cells following injury is not unique to the nervous system, although in other tissues new cells are often effective at repairing damage. This regenerative capacity is most dramatic in the hematopoietic system, where a few stem cells can repopulate the entire adaptive immune system. In contrast, it has long been believed that the generation of neurons is complete by birth. Because of this, approaches to regeneration have often focused on finding ways to spare neurons that would otherwise die.

This traditional view is changing, prompted by Joseph Altman's discovery in the 1960s that neurogenesis continues into adulthood in some parts of the mammalian brain (Figure 57–11). This finding challenged fundamental tenets of existing dogma, and the idea that new neurons could form in the hippocampus and olfactory bulb of postnatal rodents was met with skepticism for three decades.

More recently, however, the application of better cell labeling technologies has amply confirmed Altman's results and extended them to nonhuman primates and, even in a limited way, to humans via material obtained at autopsy. In the dentate gyrus of the hippocampus, for example, precursor cells divide throughout life. Some die soon after they are born and others become glial cells, but a substantial minority differentiate into granule cells that are indistinguishable from those born at embryonic stages (Figure 57–12).

Dentate

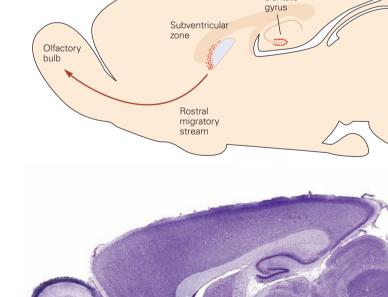

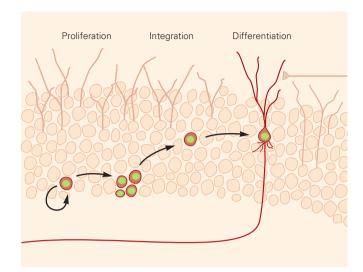

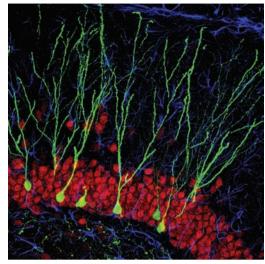

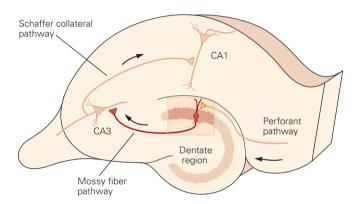

Figure 57–11 Neurons are born in the adult rodent brain at two sites. Neurons born in the subventricular zone migrate rostrally to populate the olfactory bulb. Neurons born in the hippocampus populate the dentate gyrus. (Bottom micrograph reproduced, with permission from Elsaesser and Paysan, 2007, and BrainMaps.org)

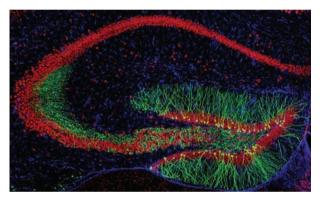

Figure 57–12 Neurons born in the germinal zone of the dentate gyrus in adult rodents are integrated into hippocampal circuits. The diagrams on the left show the pathways of neuronal differentiation and integration into dentate gyrus

circuits. In the images on the right newly generated neurons and their dendritic arbors are labeled with a virus expressing green fluorescence protein. (Micrographs courtesy of F. Gage, reproduced with permission.)

New neurons are also added to the adult olfactory bulb. They are generated in a subventricular zone far from the bulb itself, then migrate to their destination (Figure 57–13). In both cases the new neurons extend axons and dendrites, form synapses, and become integrated into functional circuits. Thus neurons born at embryonic stages are gradually replaced by later-born neurons, so that the total number of neurons in these regions of the brain is maintained.

The function of neurons born in mature animals is not completely understood, but the cells appear able to recapitulate many of the properties of neurons that arise in the embryo. When the generation of new neurons in the adult is prevented, certain behaviors mediated by the olfactory bulb and hippocampus are

degraded. Conversely, some behavioral alterations are accompanied by alterations in the tempo of adult neurogenesis. Adult neurogenesis can be decreased in animal models of depression and chronic stress, whereas enrichment of the habitat of an animal or an increase in the physical activity of otherwise sedentary rodents can increase the generation of new neurons.

Where do neurons generated in the adult brain come from? The principle that embryonic neurons and glia arise from multipotential progenitors also applies to neurons born in adults. Stem cells are the source of neurons in the adult as well as the embryo. The discovery and characterization of neurogenesis from adult stem cells has influenced research on recovery from injury in two important ways.

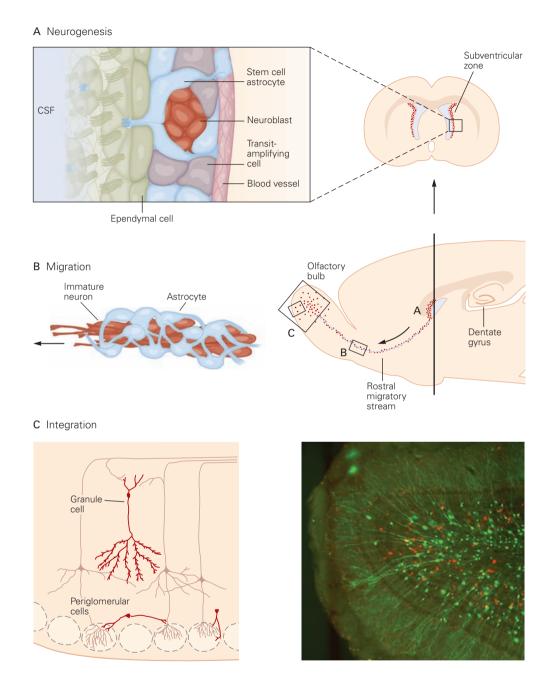

Figure 57–13 The origin and fate of neurons born in the adult ventricular zone. (Adapted, with permission, from Tavazoie et al. 2008.)

A. Neuroblasts develop in an orderly progression from astrocytic stem cells via a population of so-called transit-amplifying cells within a local niche close to blood vessels in the subventricular zone. (CSF, cerebrospinal fluid.)

B. Neuroblasts differentiate into immature neurons that migrate to the olfactory bulb using astrocytes as guides. They crawl along each other in a process called chain migration.

C. On arrival in the olfactory bulb, immature neurons differentiate into granule cells and periglomerular cells, two classes of olfactory bulb interneurons. (Image reproduced, with permission, from A. Mizrahi.)

First, the findings that endogenously generated neurons can differentiate and extend processes through the thicket of adult neuropil and can be integrated into functional circuits led researchers to speculate that the same could be true for transplanted neurons or precursors. In the past decade the idea of replacing lost neurons has progressed from science fiction to a tantalizingly testable hypothesis. Second, since neural precursors can be induced to divide and differentiate, strategies designed to augment this innate ability are now being considered, with the goal of producing neurons in large enough numbers to replace those lost to injury or neurodegenerative disease. At present such strategies are not part of clinical practice, but the intensity of the research devoted to these goals is reason for optimism.

Therapeutic Interventions May Retain or Replace Injured Central Neurons

Transplantation of Neurons or Their Progenitors Can Replace Lost Neurons

For many years neurologists have transplanted developing neurons into experimental animals to see if the new neurons could reverse the effects of injury or disease. These attempts have had promising results, most notably in the treatment of loss of dopaminer-gic cells in Parkinson disease, but their application to human patients has been fraught with difficulty.

One problem is the difficulty obtaining and growing developing neurons in sufficient numbers. Modifying neurons by introducing new genes so as to improve their chances of functioning in a new environment has also been challenging. In many cases the grafted neurons are already too mature to differentiate properly or to integrate effectively into functional circuits.

With the discovery that neural precursors transplanted into the adult brain differentiate into neurons, these obstacles may soon be overcome. Several classes of precursors have been transplanted successfully, including neural stem cells and committed precursors. In many cases these cells differentiate into neurons that are more characteristic of the transplant site than of their site of origin. This result supports the idea that the local environment plays a major role in determining neuronal cell type, and suggests that precursors need not be derived separately for each neuronal type. Conversely, the plasticity of such precursors is not unlimited, so differentiation along specific pathways needs to be established in culture before engrafting the cells.

To date this has been achieved most successfully with embryonic stem cells (ES cells). These cells are derived from early blastocyst stage embryos and can give rise to all cells of the body. In principle, the ability to direct the differentiation of ES cells along specific pathways in culture permits the generation of large numbers of cells for transplantation. Furthermore, methods for generating specific classes of neural precursors and neurons from ES cells have been devised. For example, it is possible to generate neurons that possess many or all of the properties of the spinal motor neurons that are lost in amyotrophic lateral sclerosis or to generate the dopaminergic neurons lost from the striatum in Parkinson disease, and so to engraft such neurons into the spinal cord or brain (Figure 57-14).

This technology has been enhanced recently by the molecular reprogramming of skin fibroblast cells to create induced pluripotent stem (iPS) cells (Figure 57–15). These iPS cells have a distinct advantage over ES cells; their production does not require use of embryos, effectively bypassing a minefield of practical, political, and ethical concerns that have hindered research using human ES cells. Another advantage of iPS cells is that they can be generated from an individual patient's own skin cells, neatly avoiding issues of immunological incompatibility. Many hurdles need to be overcome before iPS cells can be used clinically in regenerative medicine. Nevertheless, these cells are already being used in chemical screens to identify compounds that counteract the cellular defects that underlie human neurodegenerative disease.

Stimulation of Neurogenesis in Regions of Injury May Contribute to Restoring Function

What if, following injury in adults, one could stimulate endogenous neuronal precursors to produce neurons capable of replacing those that have been lost? Two recent findings suggest that this idea is not so far-fetched.

First, neural precursors capable of forming neurons in culture have been isolated from many parts of the adult nervous system, including the cerebral cortex and spinal cord, even though neurogenesis in adults is ordinarily confined to the olfactory bulb and hippocampus. This diversion of cell fate leads to the idea that in the adult, neurogenesis occurs in specialized niches that contain local permissive factors.

Second, the generation of new neurons can be stimulated by traumatic or ischemic injury (akin to stroke), even in areas such as the cerebral cortex or

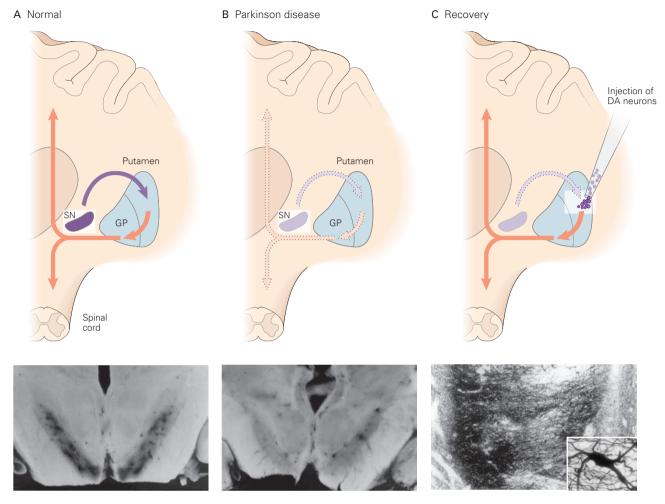

Figure 57–14 Loss of dopaminergic neurons in Parkinson disease can be treated by grafting embryonic cells into the putamen.

A. In the healthy brain dopaminergic projections from the substantia nigra (SN) innervate the putamen, which in turn activates neurons in the globus pallidus (GP). Pallidal outputs to the brain and spinal cord facilitate movement. The image below shows melanin-rich dopaminergic neurons in human substantia nigra

B. In Parkinson disease the loss of dopaminergic neurons in the substantia nigra deprives the putamen-globus pallidus

pathways of their drive. The image below shows the virtual absence of melanin-rich dopaminergic neurons in the substantia nigra of an individual with Parkinson disease.

C. Direct injection of embryonic dopaminergic neurons into the putamen reactivates the globus pallidus output pathways. The image below shows tyrosine hydroxylase expression in the cell bodies and axons of embryonic mesencephalic dopaminergic neurons grafted into the putamen of a human patient. (Image reproduced, with permission, from Kordower et al. 2000.)

spinal cord in which neurogenesis normally fails to occur. However, the fact that recovery after stroke and injury is poor demonstrates that spontaneous compensatory neurogenesis is insufficient for tissue repair. Injury-induced neurogenesis has been enhanced in experimental animals by administration of growth factors that promote neuronal production from progenitors grown in culture. If such interventions could be

adapted to humans, the range of neurons subject to replacement would be greatly increased.

Transplantation of Nonneuronal Cells or Their Progenitors Can Improve Neuronal Function

Cells other than neurons are lost after brain injury. Among the most profound losses are those of oligodendrocytes, the cells that form the myelin sheath around central axons. The stripping of myelin continues long after traumatic injury and contributes to progressive loss of function of axons that may not have been injured directly.

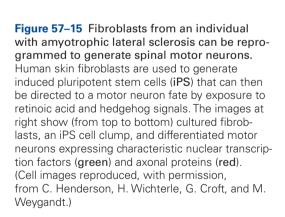

Although the adult brain and spinal cord are capable of generating new oligodendrocytes and replacing lost myelin, this cellular production line is insufficient to restore function in many cases. Since several common neurological diseases, most notably multiple sclerosis, are accompanied by a profound state of demyelination, there is strong interest in providing the nervous system with additional oligodendrocyte precursors in order to augment remyelination.

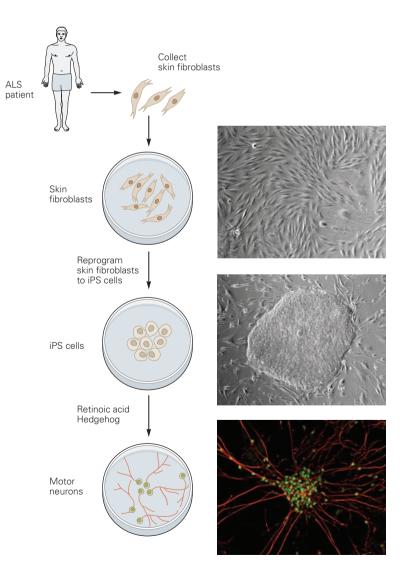

Neural stem cells, multipotential progenitors, ES cells, and iPS cells can give rise not only to neurons

but also to nonneural cells, including oligodendrocytes and their direct precursors. Indeed, at present human ES cells are being channeled into oligodendrocyte progenitor cells and implanted into injured spinal cords of experimental animals. Transplanted cells that differentiate into oligodendrocytes enhance remyelination and substantially improve the locomotor ability of experimental animals (Figure 57–16).

Restoration of Function Is the Aim of Regenerative Therapies

We need to bear in mind that efforts to replace central neurons or to enhance the regeneration of their axons would be of little use if these axons were unable to form functional synapses with their target cells.

The same fundamental questions asked about axon regeneration in adults therefore apply to synaptogenesis: Can it happen, and if not, why not?

It has been difficult to address these questions because axonal regeneration following experimentally induced injury is usually so poor that the axons never reach appropriate target fields. However, several of the studies discussed earlier in this chapter offer hope that synapse formation is possible within the dense adult neuropil. In fact, axon branches that regenerate following injury can form synapses on nearby targets. For example, Aguayo and his colleagues found that retinal axons were able to regrow into the superior colliculus when they were channeled through a peripheral nerve that had been grafted into the optic nerve (Figure 57–17A). Remarkably, some collicular neurons fired action potentials when the eye was illuminated, showing that functional synaptic connections had been reestablished (Figure 57–17B).

Likewise, neurons that arise endogenously or are implanted by investigators can form and receive synapses, raising the possibility that behaviors can be restored. Thus there is reason to believe that if injured axons can be induced to regenerate, or new neurons

Normal

supplied to replace lost ones, they will wire up in ways that help restore lost functions and behaviors.

An Overall View

Axons can regenerate and form new synapses following injury, but regeneration is far more widespread and effective in peripheral axons than in central axons. Recent studies have identified several key factors that limit regeneration of central axons. These include insufficient supplies of growth-promoting factors, pathways laden with growth-inhibitory factors, impenetrable scars, and an intrinsic reluctance of adult central axons to grow.

This is a discouraging array of obstacles, but by understanding them we can hope to manipulate them. If this can be done, it should be possible to enhance regeneration following injury and thus provide restoration of function to many patients for whom there is currently little hope.

Given the complexity of the problem, it is perhaps overly optimistic to expect that any single intervention will suffice. Instead, combined approaches may be

Demyelination

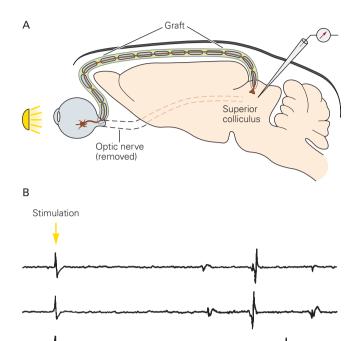

Remyelination

Figure 57–16 Restoration of myelination in the central nervous system by transplanted oligodendrocyte stem cells. In experiments on rodents with demyelinated axons, grafts of oligodendrocyte precursor cells can restore myelination to near normal. Sections through central nerve tracts are shown in the images at right. (Adapted, with permission, from Franklin and ffrench-Constant 2008.)

Figure 57–17 Regenerated retinal ganglion axons in the optic nerve can form functional synapses. (Reproduced, with permission, from Keirstead et al. 1989.)

A. A segment of optic nerve in an adult rat was removed and a segment of sciatic nerve was grafted in its place. The other end of the sciatic nerve was attached to the superior colliculus. Some retinal ganglion cell axons regenerated through the sciatic nerve and entered the superior colliculus.

B. Once the axons of the retinal ganglion neurons had regenerated, recordings were made from the superior colliculus. Flashes of light delivered to the eye elicited action potentials in collicular neurons, demonstrating that at least some regenerated axons had formed functional synapses.

needed. For example, the enzyme treatment that breaks down chondroitin proteoglycans in the glial scar is far more effective when combined with administration of neurotrophic factors. Likewise, implantation of cellular bridges that promote regeneration may need to be combined with administration of drugs to neutralize inhibitory factors that would otherwise halt growth as axons leave the bridge and enter the neuropil to form synapses.

Another consequence of axonal injury, and of many neurodegenerative diseases, is the death of neurons. This is particularly serious because in most parts of the brain and spinal cord the neurons we are born with are the only ones we will ever have. Here two new developments provide hope where there had been little: the discovery that new neurons are formed and integrated into functional circuits in a few parts of the brain, and the suite of technological advances that has allowed large numbers of neural precursors to be generated for implantation.

Finally, we should not avoid the relationship between the failure of regeneration following injury and the stabilization of connections that occurs at the end of critical periods. Myelination, which occurs largely at the end of a critical period, may have the secondary effect of preventing further, large-scale rearrangement of synaptic connections. Likewise, astrocytes may not only nurture synapses but also contribute proteoglycans that limit the ability of axons to reach out to new targets. Thus, caution will be needed to ensure that treatments aimed at fostering recovery following injury do not end up promoting formation of maladaptive circuits.

Sexual Dimorphism in the Human Brain May Correlate with Gender Identity and Sexual Orientation

An Overall View

The word "sex." Sexual activity is a biological imperative and a major human preoccupation. The physical differences between men and women that underlie partner recognition and reproduction are obvious to all of us, and their developmental origins are well understood. In contrast, our understanding of behavioral differences between the sexes is

primitive. In many cases their very existence remains controversial, and the origins of those that have been clearly demonstrated remain unclear.

In this chapter we first briefly summarize the embryological basis of sexual differentiation. We then discuss at greater length the behavioral differences between the two sexes, focusing on those differences or dimorphisms for which some neurobiological basis has been found. These dimorphisms include physiological responses (erection, lactation), drives (maternal behavior), and even more complex behaviors (gender identity). In analyzing these dimorphisms we will discuss three issues.

First, what are the genetic origins of sexual differences? Human males and females have a complement of 23 chromosomal pairs, and only one differs between the sexes. Females have a pair of X chromosomes (and are therefore "XX"), whereas males have one copy of the X chromosome paired with a Y chromosome (XY). The other 22 chromosome pairs, called *autosomes*, are shared between males and females. We will see that some genetic determinants arise from the presence of a Y chromosome, while others arise from sex-specific patterns of autosomal gene expression that exert their impact during development.

Second, how are differences in genes and gene expression translated into differences between the brains of men and women? We will see that key intermediates are the sex hormones, a set of steroids that includes testosterone and estrogens. These hormones act during embryogenesis as well as postnatally, first organizing the physical development of both genitalia and brain regions, and later activating particular physiological and behavioral responses. Hormonal

regulation is especially complex because the nervous system, which is profoundly influenced by sex steroids, also controls their synthesis. This feedback loop may help to explain how the external environment, including social and cultural factors, can ultimately shape sexual dimorphism at a neural level.

Third, what are the crucial neural differences that underlie sexually dimorphic behaviors? Clear physical and molecular differences between the brains of men and women have been found. These differences imply that neural circuitry differs between the sexes, and in a few cases these distinctions in connectivity are directly related to behavioral differences. In other cases, however, sexually dimorphic behaviors appear to result from differential usage of the same basic circuits.

Before proceeding we must define the usage of two words that are commonly confused with each other: sex and gender. As a descriptor of biological differences between men and women, the word sex is used in three ways. First, anatomical sex refers to overt differences including the differences in the external genitalia as well as other sexual characteristics such as the distribution of body hair. Gonadal sex refers to the presence of male or female gonads, the testes or ovaries. Finally, chromosomal sex refers to the distribution of the sex chromosomes between females (XX) and males (XY).

Whereas *sex* is a biological term, *gender* encompasses the collection of social behaviors and mental states that typically differ between males and females. *Gender role* is the set of behaviors and social mannerisms that is typically distributed in a sexually dimorphic fashion within the population. Toy preferences in children as well as distinctive attire are some examples of gender roles that can distinguish males from females. *Gender identity* is the feeling of belonging to the category of the male or female sex. Importantly, gender identity is distinct from *sexual orientation*, the erotic responsiveness displayed toward members of one or the other sex.

Are gender and sexual orientation genetically determined? Or are they social constructs molded by cultural expectations and personal experience? As the examples in this chapter will illustrate, we are still far from untangling the contributions of genes and environment to such complex phenomena. However, our recognition that genes and experience interact to shape neural circuits gives us a more realistic framework with which to answer this question compared to our predecessors, who were constrained by the simplistic view that genes and experience acted in mutually exclusive ways.

Genes and Hormones Determine Physical Differences Between Males and Females

Chromosomal Sex Directs the Gonadal Differentiation of the Embryo

Sex determination is the embryonic process whereby chromosomal sex directs the differentiation of the gonadal sex of the animal. Surprisingly, this process differs in fundamental ways within the animal kingdom and even among vertebrates. In most mammals, including humans, however, an XY genotype drives differentiation of the embryonic gonad into testes, whereas an XX genotype leads to ovarian differentiation. Hormones produced by the testes and ovaries subsequently direct sexual differentiation of the nervous system and the rest of the body.

It is the presence of the Y chromosome rather than the lack of a second X chromosome that is the crucial determinant of male differentiation. This was first evident in rare individuals born with two or even three X chromosomes in addition to a Y chromosome (XXY or XXXY). These individuals are men who exhibit male-typical traits. In fact, female cells do not have two active X chromosomes. Early in embryogenesis one of the two X chromosomes in each female cell is chosen at random for inactivation and the genes on it are rendered transcriptionally silent. Thus both male and female cells have a single active X chromosome and male cells also have a Y chromosome.

The sex-determining activity of the Y chromosome is encoded by the gene *SRY* (sex-determining region on Y) whose activity is required for masculinization of the embryonic gonads (Figure 58–1). Inactivation or deletion of *SRY* leads to complete sex reversal: Individuals are chromosomally male (XY) but externally indistinguishable from females. Conversely, in rare instances *SRY* translocates to another chromosome (to the X chromosome or an autosome) during spermatogenesis. Such sperm can fertilize eggs to produce individuals who are chromosomally female (XX) but externally male. However, such XX sex-reversed men are infertile, as many of the genes required for sperm function are located on the Y chromosome.

How does *SRY* instruct the undifferentiated gonads to develop into testes? The female differentiation program appears to be the default mode; patterning genes prime the body and gonads to develop along female-specific pathways. The *SRY* gene encodes a transcription factor that induces expression of genes, some of which prevent execution of the default program and initiate the process of male gonadal differentiation. One of the best-studied targets of the SRY transcription

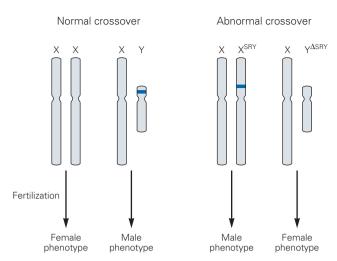

Figure 58–1 The role of the *SRY* gene in sex determination in humans. *SRY*, the sex-determining locus (blue domain), resides on the nonhomologous region of the short arm of the Y chromosome. The presence of *SRY* is determinative for male differentiation in many mammals, including primates and most rodents. Normally X- or Y-bearing sperm fertilize an oocyte to generate XX females or XY males, and the resulting phenotypic sex is concordant for the chromosomal sex. Rarely *SRY* translocates to the X chromosome or an autosome (not shown). In such cases XX^{SRY} offspring are phenotypically male while XY^{ΔSRY} offspring (the Δ indicating a gene deletion) are phenotypically female. (Modified, with permission, from Wilhelm, Palmer, and Koopman 2007.)

factor is another transcription factor, SOX9, which is required for differentiation of the testes. SOX9 in turn activates a variety of genes required for formation of testicular Sertoli cells. Thus SRY initiates a cascade of inductive interactions that ultimately lead to male-specific gonad development.

Gonads Synthesize Hormones That Promote Sexual Differentiation

The chromosomal complement of the embryo directs sexual differentiation of the gonads and in turn the gonads determine the sex-specific features of the nervous system and the rest of the body. They do this by secreting hormones. Gonadal hormones have two major roles. Their developmental role is traditionally referred to as *organizational* because the early effects of hormones on the brain and the rest of the body lead to major, generally irreversible, aspects of cell and tissue differentiation. Later some of the same hormones trigger physiological or behavioral responses. These influences, generally termed *activational*, are reversible.

One example of an organizational role of gonadal hormones is seen in the differentiation of structures that connect the gonads to the external genitalia. In males the Wolffian duct gives rise to the vas deferens, the seminal vesicles, and the epididymis. In females the Müllerian duct differentiates into the oviduct, the uterus, and the vagina (Figure 58-2). Initially both female (XX) and male (XY) embryos possess Wolffian and Müllerian ducts. In males the developing testes secrete a protein hormone, the Müllerian inhibiting substance (MIS), and a steroid hormone, testosterone. MIS leads to a regression of the Müllerian duct and testosterone induces the Wolffian duct to differentiate into its mature derivatives. In females the absence of MIS permits the Müllerian duct to differentiate into its adult derivatives, and the absence of circulating testosterone causes the Wolffian duct to resorb. Thus the Y chromosome overrides a female default program to generate male gonads, which in turn secrete hormones that override a female default program of genital differentiation.

The action of MIS is largely confined to embryos, but steroid hormones exert effects throughout life—that is, they have activational as well as organizational roles. All of the steroid hormones derive from cholesterol (Figure 58–3). The sex steroids can be divided into androgens, which generally promote male characteristics, and the estrogens plus progesterone that promote female characteristics. The testes produce mostly the androgen testosterone, while the ovaries produce mostly progesterone and an estrogen, 17- β -estradiol. The menstrual cycle is a good example of the activational function of estrogen and progesterone.

A glance at the metabolic relationships among steroid hormones (Figure 58–3) reveals a surprise. The female hormone progesterone is the precursor of the male hormone testosterone, and testosterone is the direct precursor of the female hormone 17-β-estradiol. Thus the enzymes that convert one hormone to the other control not only the level of the hormone but also the "sign" (male or female) of the hormonal effect. Aromatase, the enzyme that converts testosterone to estradiol, is present at high levels in the ovaries but not in the testes. Differential expression of aromatase is the reason for sexual dimorphism in circulating testosterone and estrogen. Aromatase is also expressed in various regions of the brain (Figure 58–4A), and many of the effects of testosterone on neurons are thought to occur after its conversion to estrogen. Testosterone is also converted by the enzyme 5α -reductase into another androgenic steroid, 5α-dihydrotestosterone (DHT), in various target tissues, including the external genitalia. In these tissues DHT is responsible for induction of secondary male characteristics such as facial and body hair and growth of the prostate. Later in life DHT is the culprit in male pattern baldness.

As one can imagine, mutations in genes encoding enzymes involved in steroid hormone biosynthesis have far-reaching consequences. The phenotypes dramatically illustrate both the organizational and activational effects of steroid hormones, as well as the difficulty of neatly distinguishing the two. Here we describe three disorders (Table 58–1).

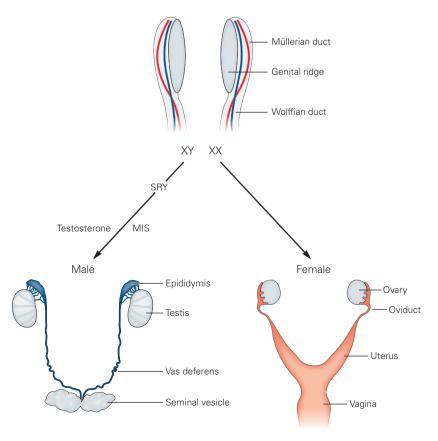

The first, congenital adrenal hyperplasia or CAH, is a genetic deficiency in the synthesis of corticosteroids by the adrenal glands that results in overproduction of testosterone and related androgens. This condition is autosomal recessive and occurs once in 10,000–15,000 live births. In girls born with CAH, excess androgens lead to some masculinization of the external genitalia, a process called *virilization*. Virilization clearly reflects the organizational roles of steroids. This condition can be diagnosed at birth and resolved by surgical intervention. Treatment with corticosteroids reduces testosterone levels, permitting these females to undergo puberty and to be fertile.

A second genetic disorder, 5α -reductase II deficiency, can also affect sexual differentiation (Table 58–1). In male fetuses 5α -reductase II is expressed at high levels in the precursor of the external genitalia, where it converts circulating testosterone into DHT. The high local concentrations of DHT virilize the external genitalia. Clinical 5α -reductase II deficiency is inherited in an autosomal recessive manner, and males present at birth with ambiguous (under-virilized) or overtly feminized external genitalia. In many instances, therefore, chromosomally male patients (XY) with this condition are mistakenly raised as females until puberty, at which time the large increase in circulating testosterone virilizes the body hair, musculature, and, most dramatically, the external genitalia.

Steroid Hormones Act by Binding to Specific Receptors

The critical role of steroid receptors in controlling sexual differentiation is well illustrated by patients with a third disorder, complete androgen insensitivity syndrome or CAIS (Table 58–1). Testosterone, estrogen,

Figure 58–2 Sexual differentiation of the internal genitalia. Embryos of both sexes develop bilateral genital ridges (the gonadal anlagen) that can differentiate into either testes or ovaries; Müllerian ducts, which can differentiate into oviducts, the uterus, and the upper vagina; and Wolffian ducts, which can differentiate into the epididymis, the vas deferens, and the seminal vesicles. In XY embryos the expression of the SRY gene in the genital ridge induces differentiation of this tissue into testes and of the Wolffian ducts into the rest of the male internal genitalia, while the Müllerian ducts are resorbed. In XX embryos the absence of SRY permits the genital ridges to develop into ovaries and the Müllerian ducts to differentiate into the rest of the female internal genitalia; in the absence of circulating testosterone the Wolffian ducts degenerate. (MIS, Müllerian inhibiting substance.) (Modified, with permission, from Wilhelm, Palmer, and Koopman 2007.)

and progesterone are hydrophobic molecules that are able to diffuse across cell membranes, enter the blood-stream, enter cells in many organs, and bind to intracellular ligand-specific receptors. The receptors for these hormones are encoded by distinct but homologous genes.

A single gene encodes a receptor that binds the androgens testosterone and DHT. The androgen receptor binds DHT approximately threefold more tightly than testosterone, accounting for the greater potency of DHT. There is also a single receptor for progesterone

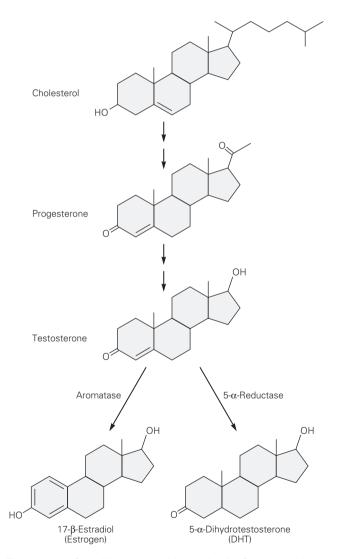

Figure 58–3 Steroid hormone biosynthesis. Cholesterol is the precursor of all steroid hormones and is converted via a series of enzymatic reactions into progesterone and testosterone. Testosterone or related androgens are obligate precursors of all estrogens in the body, a conversion that is catalyzed by aromatase. The expression of 5- α -reductase in target tissues converts testosterone into dihydrotestosterone, an androgen.

(progesterone receptor), whereas two genes encode receptors that bind estrogens (estrogen receptors α and β). The estrogen receptors are present in many tissues of the body, including the brain (Figure 58–4B).

These receptor proteins are transcription factors that bind specific sites in the genome and modulate transcription of target genes. They contain several signature motifs, including a hormone-binding domain, a DNA-binding domain, and a domain that modulates the transcriptional activity of target genes (Figure 58–5A). Hormones activate the transcriptional activity by binding to the receptor. In the absence of ligand the receptors bind to protein complexes that sequester them in the cytoplasm. Upon binding of ligand the receptors dissociate from the complex and enter the nucleus, where they dimerize and bind to specific sequence elements in the promoter and enhancer regions of target genes, modulating their transcription (Figure 58–5B).

Patients with CAIS are chromosomally XY but carry a loss-of-function allele of the X-linked androgen receptor that abolishes cellular responses to testosterone and DHT. Because the pathway of sex determination via *SRY* remains functional, these patients have testes. However, because of androgen signaling, the Wolffian ducts do not develop, the testes fail to descend, and the external genitalia are feminized. In adulthood most of these patients opt for surgical removal of the testes and hormonal supplementation appropriate for females.

Sexual Differentiation of the Nervous System Generates Sexually Dimorphic Behaviors

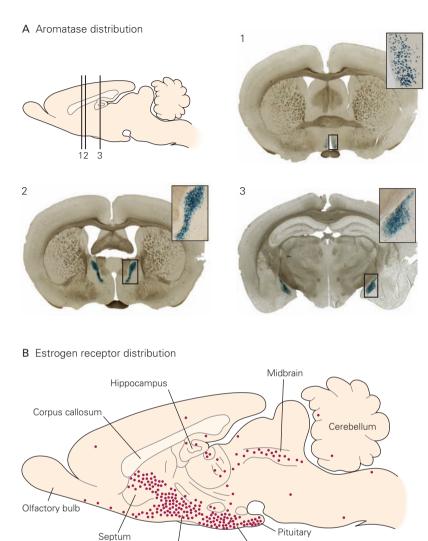

Sex-specific behaviors occur because the nervous system differs between males and females. These differences arise from a combination of genetic factors, such as components of the sex determination pathways, as well as environmental factors, such as social experience. In many cases both genetic and environmental inputs act through the steroid hormone system to sculpt the nervous system. Many anatomical instances of sexual dimorphism have been documented, including differences in the numbers and size of neurons in particular structures as well as differences in the pattern and number of synapses.

It is challenging to trace the chain of causality from environmental or genetic factors to the development of neural dimorphisms and to link these differences to sex-specific behaviors. In this section we examine a few cases in which studies in experimental animals have provided insights. In later sections we ask

Figure 58–4 Aromatase and estrogen receptors are expressed in specific regions of the brain.

A. The enzyme aromatase, which catalyzes the conversion of testosterone into estrogen (see Figure 58–3), is expressed in discrete neuronal populations in the brain. Aromatase labeled with a reporter protein (blue) in transgenic mice is shown here in three coronal planes of the brain: in neurons in the preoptic hypothalamus (1), in the bed nucleus of the stria terminalis or BNST (2), and in the medial amygdala (3). These areas contain sexually dimorphic neurons that regulate sexual behavior, aggression, and maternal behaviors. (Modified, with permission, from Wu et al. 2009.)

B. This midsagittal section of an adult rat brain shows binding of estrogen to cells in various hypothalamic regions, including the preoptic area, which is sexually dimorphic. Additional estrogen binding is seen in the septum, hippocampus, pituitary, and midbrain. Other, more lateral areas such as the amygdala (not shown) also contain estrogen receptors.

whether similar mechanisms underlie sexually dimorphic behaviors in humans.

However, before proceeding we note that the ways in which chromosomal mechanisms of sex determination are linked to the cellular processes of sexual differentiation in the central nervous system vary widely among species. In insects sex differences in behavior are independent of hormonal secretion from the gonads, and instead rely exclusively on a sex determination pathway within individual neurons. This mode of sexual differentiation of the brain and behavior is particularly well understood in the fruit fly, where it has been demonstrated that the sex determination cascade initiates expression of a single transcription factor, fruitless, that specifies the entire repertory of male sexual behaviors (Box 58–1).

A Sexually Dimorphic Neural Circuit Controls Erectile Function

Preoptic area

The lumbar spinal cord of many mammals, including humans, contains a sexually dimorphic motor center, the spinal nucleus of the bulbocavernosus (SNB). Motor neurons in the SNB innervate the bulbocavernosus muscle, which plays an important part in penile reflexes in males and vaginal movements in females.

. Hypothalamus

In adult rats the male SNB contains many more motor neurons than the female SNB. In addition, male SNB motor neurons are larger in size and have larger dendritic arbors, with a corresponding increase in the number of synapses they receive. Like the SNB motor neurons, the bulbocavernosus muscle is larger in males than females; it is completely absent in the females of

	Complete androgen insensitivity syndrome (CAIS)	5-α-reductase II deficiency	Congenital adrenal hyperplasia (CAH)
	insensitivity syndrome (CA15)	5-0-reductase if deliciency	nyperpiasia (CAII)
Chromosomal sex	XY	XY	XX
Molecular basis	Nonfunctional androgen receptor, leading to inability to respond to circulating androgens.	Nonfunctional 5- α -reductase II, leading to deficit in conversion of testosterone to 5 α -dihydrotestosterone (DHT) in target tissues.	Defect in corticosteroid synthesis, leading to increase in circulating androgens from the adrenals.
Gonad	Testis	Testis	Ovary
Wolffian derivatives	Vestigial	Present	Absent
Müllerian derivatives	Absent	Absent	Present
External genitalia:			
At birth	Feminized	Variably feminized	Variably virilized
After puberty	Feminized	Masculinized	Feminized
Gender identity	Female	Female or male	Female or male
Sexual partner preference	Male	Female or male	Female or male

Table 58-1 Three Clinical Syndromes That Highlight the Role of Androgens in Masculinization in Humans

some mammalian species. SNB motor neurons also innervate the levator ani muscle, which is involved in copulatory behavior and is also larger in males than females.

How do these differences arise? Initially the circuit is not sexually dimorphic. At birth male and female rats have similar numbers of neurons in the SNB and similar numbers of fibers in the bulbocavernosus and levator ani muscles. In females, however, many motor neurons in the SNB and many fibers in the bulbocavernosus and levator ani muscles die in early postnatal life. Thus this sexual dimorphism arises not by male-specific generation of cells but rather by female-specific cell death.

Perinatal injections of testosterone or DHT can rescue a significant number of the dying neurons and muscle fibers in the female rat. Conversely, treatment of male pups with an androgen receptor antagonist increases the number of dying neurons and muscle fibers. So at a deeper level we see that the dimorphism results from male-specific preservation of motor neurons and muscle fibers that would die in the absence of hormone.

Where does testosterone act to establish this structural dimorphism? Is it primarily a survival factor for the motor neurons, with muscle fibers dying secondarily because they lose their innervation? Or does

testosterone act on muscles, which then provide a trophic factor to support the survival of SNB motor neurons? This issue has been examined in rats carrying a mutation of the androgen receptor (*tfm* allele) that reduces binding of ligand to 10% of normal. The receptor resides on the X chromosome, so all males that carry a mutant gene on their one and only X chromosome are feminized and sterile. For female heterozygotes, the situation is more complicated. As described earlier, one of the X chromosomes is randomly inactivated in each XX female.

Female heterozygotes are therefore mosaics: some cells express a functional androgen receptor allele, others the mutated allele. Each muscle fiber has many nuclei, so most bulbocavernosus muscle fibers in the heterozygous female express functional androgen receptors. Motor neurons have a single nucleus, however, so each neuron is either normal or receptor-deficient. If androgen receptors were required in the neuron, one would expect only receptor-expressing SNB motor neurons to survive, whereas if receptors were required only in muscles, one would expect surviving motor neurons to be a mixture of wild type and mutant.

In fact, the latter situation occurs, indicating that survival of SNB motor neurons does not depend on a neuron-autonomous function of the androgen receptor. Rather, these neurons receive a trophic cue from the androgen-dependent bulbocavernosus and the levator ani muscles (Figure 58–7A). These cues may include the ciliary neurotrophic factor (CNTF) or a related molecule, because mutant male mice lacking a CNTF receptor exhibit a decreased number of SNB motor neurons, typical of females.

Male and female SNB motor neurons also differ in size. Androgens determine the differences in number and size of these neurons in different ways. Studies of *tfm* mutants showed that androgens exert an organizational effect during early postnatal life through a direct effect on muscle. Low levels of androgens during this critical period lead to an irreversible reduction in the number of SNB motor neurons. Later, androgens act directly on SNB motor neurons to increase the extent of their dendritic arbors. A loss of circulating testosterone, such as that occurring after castration, leads to a dramatic pruning of dendritic arbors; injection of supplemental testosterone to a castrated male rat can restore this dendritic branching pattern (Figure 58–7B). This effect persists in adulthood and

is reversible, so it can be viewed as an activational influence. Thus androgens can exert diverse effects, even on a single neuronal type.

A Sexually Dimorphic Neural Circuit Controls Song Production in Birds

Several species of songbirds learn species-specific vocalizations that are used for courtship rituals and territorial marking (see Chapter 60). A set of interconnected brain nuclei controls the learning and production of birdsong (Figure 58–8A). In some songbird species both sexes sing and the structure of the song circuit is similar in males and females. In other species, such as zebra finches and canaries, males alone sing. In these species several song-related nuclei are significantly larger in the male than in the female.

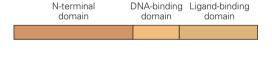

The development of sexual dimorphism in song circuitry has been studied in detail in the zebra finch. In the adult male zebra finch the robust nucleus of the archistriatum (RA) contains fivefold more neurons than does the same nucleus in females. In addition,

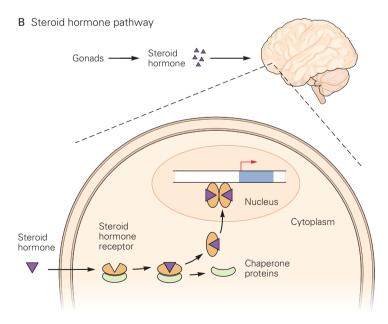

Figure 58–5 Steroid hormone receptors and their mechanism of action.

A. The canonical receptors for steroid hormones are ligand-activated transcription factors. These receptors have an N-terminal domain, which contains a transcriptional transactivator domain; a central DNA-binding domain; and a C-terminal ligand-binding domain, which may contain an additional transcriptional transactivator domain.

B. Sex steroid hormones are hydrophobic and enter the circulation by diffusing across the plasma membrane of steroidogenic cells in the gonads. They enter target cells in distant tissues such as the brain by passing through the plasma membrane and bind their cognate receptors. The steroid hormone receptor typically exists in a multiprotein complex with chaperone proteins in the cytoplasm of hormone-responsive cells. Ligand-binding promotes dissociation of the receptor from the chaperone complex and translocation into the nucleus. In the nucleus the receptor is thought to bind to hormone response elements as a homodimer to modulate transcription of target genes. (Modified, with permission, from Wierman 2007.)

Box 58–1 Genetic and Neural Control of Mating Behavior in the Fruit Fly

In the presence of a female fruitfly the adult male fly engages in a series of essentially stereotyped routines that usually culminate in copulation (Figure 58–6A). This elaborate male courtship ritual is encoded by a cascade of gene transcription within the brain and peripheral sensory organs that masculinizes the underlying neural circuitry.

Sex determination in the fly does not depend on gonadal hormones, as it does in vertebrates. Instead, it occurs cell autonomously throughout the body. In other words, sexual differentiation of the brain and the rest of the body is independent of gonadal sex. The malespecific Y chromosome of fruit flies does not bear a sexdetermining locus. Instead, sex is determined by the ratio of X chromosome number to autosome number (X:A). A ratio of 1 is determinative for female differentiation, whereas a ratio of 0.5 drives male differentiation.

The X:A ratio sets into motion a cascade of gene transcription and alternative splicing programs that leads to the expression of sex-specific splice forms of two genes, *doublesex* (*dsx*) and *fruitless* (*fru*). The *dsx* gene encodes a transcription factor that is essential for sexual differentiation of the nervous system and the rest of the body, with the sex-specific splice variants responsible for male- and female-typical development.

The fru gene encodes a set of putative transcription factors that is generated by multiple promoters and alternative splicing. In males one particular mRNA ($fru^{\rm M}$) is translated into functional proteins. In female flies alternative splicing results in the absence of such proteins.

Males carrying a genetically modified fru allele that can only be spliced in the female-specific manner (fru^F) have essentially normal, dsx-dependent sexual differentiation. These fru^F males therefore resemble wild type males externally. However, the loss of Fru^M in these animals abolishes male courtship behavior directed toward females. These data indicate that Fru^M is required for male courtship and copulation.

Conversely, transgenic female flies carrying a *fru*^M allele exhibit male mating behavior toward wild type females, indicating that *fru*^M is sufficient to inhibit female sexual responses and promote male mating.

Intriguingly, fru^F males do not court females and, like wild type females, do not reject mating attempts by wild type males or fru^M females. Similarly, fru^M females attempt to mate with both fru^M and wild type females. These data suggest that fru^M may also specify sexual partner preference, which in the case of wild type males would be directed to females.

In wild type females without fru^{M} the neural pathways are wired such that these flies exhibit sexually receptive behaviors toward males. When groups of fru^{F} males (or fru^{M} females) are housed together, they court each other vigorously, often forming long chains of flies attempting copulation.

To build the circuitry underlying male courtship rituals, $fru^{\rm M}$ appears to initiate cell-autonomous male-typical differentiation of the neurons in which it is expressed. This leads to overt neuroanatomic dimorphism in cell number or projections of several specific classes of neurons (Figure 58–6B). Many neurons that express $fru^{\rm M}$ are not distributed in dimorphic patterns. In these neurons $fru^{\rm M}$ may regulate the expression of particular classes of genes whose products drive a male-specific program of physiology and function.

Are neurons that express $fru^{\rm M}$ required for male courtship behavior? When synaptic transmission is genetically blocked in these neurons in adult males all components of courtship behavior are abolished. Importantly, these males continue to exhibit normal movement, flight, and other behaviors in response to visual and olfactory stimuli. These findings demonstrate that $fru^{\rm M}$ appears to be expressed in a neural circuit that is essential for and dedicated to male fly courtship.

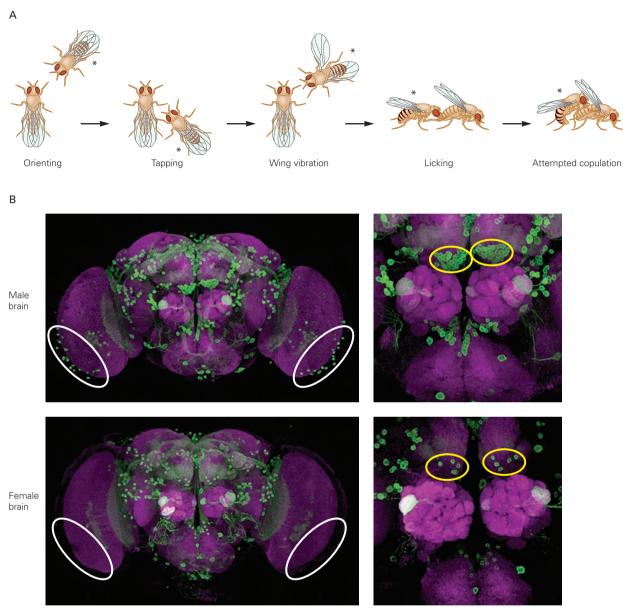

Figure 58–6 Control of male courtship in the fruit fly. A. Male *Drosophila melanogaster* (labeled with **asterisk**)

A. Male *Drosopnia melanogaster* (labeled with asterisk) engage in a stereotyped sequence of behavioral routines that culminate in attempted copulation. The male fly orients toward the female and then taps her with his forelegs. This is followed by wing extension in the male and a species-specific pattern of wing vibrations that is commonly referred to as the fly courtship song. If the female fly is sexually receptive, she slows down and permits the male to lick her genitalia. The female then opens her vaginal plates in order to allow the male to initiate copulation. All steps in the male mating ritual require the expression of a sex-specific splice variant of the *fruitless* (*fru*) gene. (Modified, with permission, from Greenspan and Ferveur 2000.)

B. The *fru* gene encodes a male-specific splice variant that is necessary and sufficient to drive most steps in the male fly courtship ritual. *Fru* expression is visualized using a fluorescent reporter protein (green) in transgenic flies. *Fru*-expressing neuronal clusters are present in comparable numbers in the central nervous system of both male and female flies. However, there are sex differences in *Fru* expression as well. A cluster of *Fru*-expressing neurons is present in the male optic lobes (in the area within the white ellipses) but absent in the corresponding regions in the female brain. The two male antennal lobe regions (areas within yellow ellipses) contain about 30 neurons each, whereas each female region has only 4–5 neurons. (Modified, with permission, from Kimura et al. 2005.)

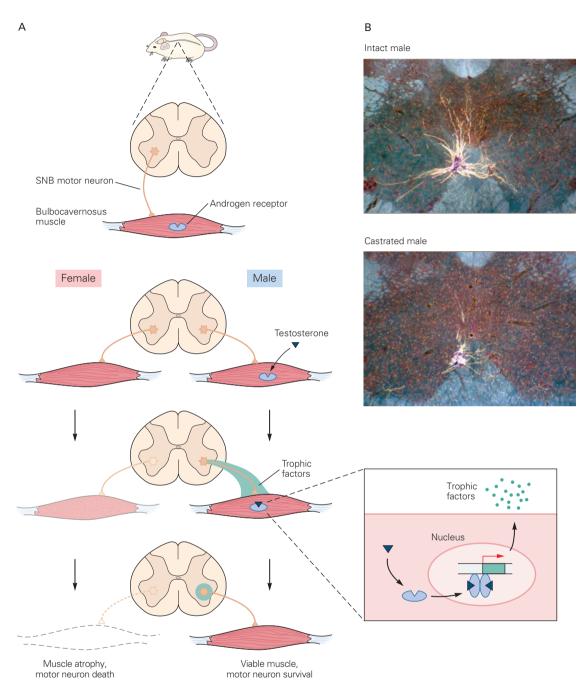

Figure 58–7 Sexual dimorphism in the spinal nucleus of the bulbocavernosus muscle.

A. The spinal nucleus of the bulbocavernosus (SNB) is found in the male lumbar spinal cord but is greatly reduced in the female. The motor neurons of the nucleus are present in both sexes at birth but the lack of circulating testosterone in females leads to death of the SNB neurons and their target muscles. It is thought that testosterone in the male circulation promotes the survival of the target muscles, which express the androgen receptor. In response to testosterone the muscles provide trophic support to the innervating SNB neurons. This musclederived survival factor is likely to be ciliary neurotrophic factor or a related member of the cytokine family. Thus testosterone

acts on muscle cells to control the sexual differentiation of SNB neurons. (Reproduced, with permission, from Morris, Jordan, and Breedlove 2004.)

B. Dendritic branching of SNB neurons is regulated by circulating testosterone in adult male rats. In males the dendrites arborize extensively within the spinal cord (upper photo). The fact that the arbors are pruned in adult castrated male rats (lower photo) is evidence that this dendritic branching depends on androgens. The spinal cord is shown in transverse section and the SNB neurons and their dendrites are labeled by a retrograde tracer injected into target muscles. (Reproduced, with permission, from Cooke and Woolley 2005.)

the afferent projections to RA exhibit a striking sexual dimorphism—only in males does the RA receive input from high vocal centers (HVCs) (Figure 58–8B). These sex differences in cell number and connectivity of RA are not evident until after hatching, when in females a large number of RA neurons die and in males the axons of HVC neurons enter the RA nucleus.

These sexually dimorphic anatomical features are regulated by steroid hormones. When females are supplied with estrogen (or an aromatizable androgen such as testosterone) after hatching, the number of neurons in the RA and the termination pattern in the nucleus are similar to that of the male. However, early hormone administration to young females is not sufficient to masculinize the song nuclei to a size comparable to that of adult males, nor is it sufficient to induce singing in females. To achieve these functions, female birds that receive testosterone or estradiol after hatching must also receive testosterone or dihydrotestosterone (but not estrogen) as adults. Thus steroids play both organizational and activational roles in this system.

A Sexually Dimorphic Neural Circuit in the Hypothalamus Controls Mating Behavior

In many mammalian species the preoptic region of the hypothalamus and a reciprocally connected region, the bed nucleus of the stria terminalis (BNST), play important roles in sexually dimorphic mating behaviors. In male rodents and monkeys these areas are activated during mating behavior; surgical lesions that ablate the preoptic region or the BNST result in deficits in male sexual behavior in male rodents, and also disinhibit female-type sexual receptivity. Thus this region contains neurons that activate and inhibit female sexual behavior. Surgical lesioning of the preoptic hypothalamic region activates male mating routines and inhibits female sexual receptivity in rodents.

Both the preoptic hypothalamus and the BNST are sexually dimorphic, containing more neurons in males compared to females. The sexually dimorphic nucleus of the preoptic area (SDN-POA) also contains significantly more neurons in the male. A male-specific perinatal surge of testosterone promotes survival of neurons in the SDN-POA, whereas in females these same cells gradually die off in the early postnatal period. This development is similar to that in the sexually dimorphic nuclei of the rodent spinal cord and the songbird brain, suggesting that androgen control is a common mechanism for production of sex differences in the size of neuronal populations.

Curiously, the ability of brain testosterone to promote the survival of neurons is likely to be exerted via

aromatization into estrogen and subsequent activation of the estrogen receptors (see Figure 58–5). How, then, is the neonatal female brain shielded from the effects of circulating estrogen? In newborn females there is very little estrogen in the circulation, and the small amount present is sequestered by binding to α -fetoprotein, a serum protein. This explains why female mice lacking α -fetoprotein exhibit male-specific behaviors and reduced female-typical sexual receptivity. In this case, then, structural sexual dimorphism does not result from differential effects of androgens and estrogens, but rather from sex differences in the level of hormone available to the target tissue.

Environmental Cues Control Some Sexually Dimorphic Behaviors

Sex-specific behaviors are usually initiated in response to sensory cues in the environment. There are many such cues, and distinct sensory modalities are used in a species-specific manner to elicit a similar response. Courtship rituals can be triggered by species-specific vocalizations, visual signals, odors, and even, in the case of weakly electric fish, by electric discharges. Recent genetic and molecular studies have led to significant insight into how sensory experience controls some of these behaviors in rodents. Here we discuss two examples: the regulation of partner choice by pheromones and the regulation of maternal behavior by experience during infancy.

Pheromones Control Partner Choice in Mice

Many animals rely on their sense of smell to move about, obtain food, and avoid predators. They also rely on pheromones—chemicals that are produced by an animal to affect the behavior of another member of the species. In rodents pheromones can trigger many sexually dimorphic behaviors, including mate choice and aggression (the propensity of males to fight over territory or mates and the tendency of nursing females to attack nest intruders).

Pheromones are detected by neurons in two distinct sensory tissues in the vertebrate nose: the main olfactory epithelium (MOE) and the vomeronasal organ (VNO) (Figure 58–9A). It is thought that sensory neurons in the MOE detect volatile odors whereas those in the VNO detect nonvolatile chemosensory cues. Removal of the olfactory bulb, the only synaptic target of neurons in the MOE and the VNO, abolishes mating as well as aggression in mice and other rodents. These and other studies indicate an essential role for olfactory stimulation in initiating mating and fighting.

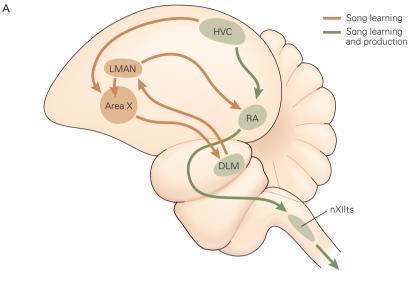

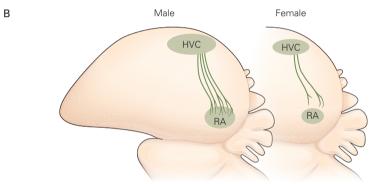

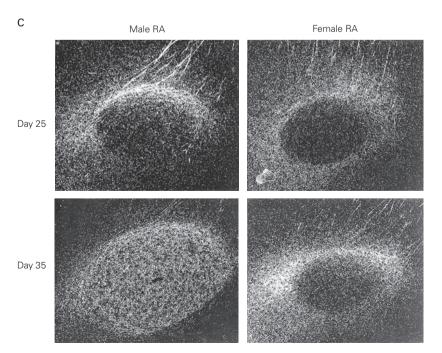

Figure 58–8 Sexual dimorphism in the avian song circuit.

A. Songbirds have a dedicated neural circuit for song production and learning, with distinct components contributing to learning or production. Many of these components are sexually dimorphic in songbirds in which only one sex sings. For example, in zebra finches the male sings, and the male high vocal center (HVC), robust nucleus of the archistriatum (RA), lateral magnocellular nucleus of the anterior neostriatum (LMAN), and area X are larger in volume and contain more neurons than the comparable regions in the female. (DLM, medial nucleus of the dorsolateral thalamus; nXIIts, hypoglossal nucleus.) (Reproduced, with permission, from Brainard and Doupe 2002.)

B. In the male the axons of HVC neurons terminate on neurons in the RA nucleus, whereas in females the axons terminate in a zone surrounding the nucleus. The sexual dimorphism in cell number and connectivity of these regions is regulated by estrogen. (Reproduced, with permission, from Morris, Jordan, and Breedlove 2004.)

C. The pattern of termination of the axons of HVC neurons in the RA nucleus varies in males and females at different ages after hatching. (Reproduced, with permission, from Konishi and Akutagawa 1985.)

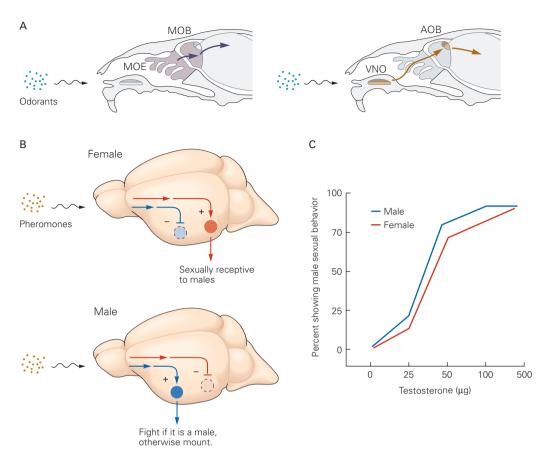

Figure 58–9 Pheromonal and hormonal control of male and female sexual behavior.

A. Odorants are detected by sensory neurons in the main olfactory epithelium (MOE), which projects to the main olfactory bulb (MOB), and by neurons in the vomeronasal organ (VNO), which projects to the accessory olfactory bulb (AOB). Many of the central connections of the MOE and VNO pathway are anatomically segregated. (Modified, with permission, from Dulac and Wagner 2006.)

B. Female mice possess the neural circuitry that can activate either male (blue) or female (red) mating behaviors. In wild type females pheromones activate female mating behavior and inhibit male-type mating. By contrast, in males pheromones activate a circuitry that will initiate fights with males and mating

with females. (Modified, with permission, from Kimchi, Xu, and Dulac 2007.)

C. Testosterone activates male sexual behavior in male and female mice. The data are from a study in which the gonads of male and female mice were surgically removed in adulthood. None of the animals exhibited male sexual behavior with wild type females following surgery. After administration of testosterone, mating behavior was restored in castrated males, and females displayed male sexual behavior. This effect was dosedependent; at the highest dose male and female mice exhibited comparable levels of male-type mating behavior toward wild type females. (Modified, with permission, from Edwards and Burge 1971.)

Genetically engineered disruption of pheromone responsiveness in the MOE or VNO reveals that these sensory tissues have a surprisingly complex role in the mating behavior of mice. A functional MOE is essential to trigger male sexual behavior, and an intact VNO is required for sex discrimination and directing the male to mate with females.

Key to these experiments is the fact that olfactory neurons in the MOE and the VNO use different signal transduction cascades to convert olfactory input into electrical responses. The cation channel Trpc2 appears essential for pheromone-evoked signaling in VNO neurons; it is not expressed in MOE neurons, which use a different signal transduction apparatus. Thus mice lacking the gene *trpc2* have a nonfunctional VNO and an intact MOE. Mating behavior directed to animals of the opposite sex appears unaltered in *trpc2* mutant males as well as females. However, both males and female mutants often exhibit male sexual behavior with members of either sex. For example,

trpc2 mutant females mate with females in a manner seemingly indistinguishable from wild type males, except of course the females cannot ejaculate. These and other findings suggest that the VNO is used to discriminate among sexual partners. When the VNO is inactivated animals can no longer distinguish between males and females, and mutants therefore exhibit male sexual behavior toward members of both sexes. Similarly, adult wild type females treated with testosterone also exhibit male sexual behavior toward females (Figure 58–9C).

One implication of these studies is that female mice possess the neural circuitry for male sexual behavior (Figure 58-9B). Activation of this neural circuit is inhibited in wild type females by sensory input from the VNO and by the lack of testosterone. Removal of the VNO or administration of testosterone activates male sexual behavior in females. Male mating behavior has been observed in females of many species, indicating that the findings in mice are likely to be of general relevance. Thus neural pathways for male and female mating behavior appear to be present in both sexes. The female-typical behavior of male rats following hypothalamic lesions is another example. In such cases it is the differential regulation of these circuits that underlies the sexually dimorphic expression of male and female sexual behaviors.

Early Experience Modifies Later Maternal Behavior

The preoptic area of the hypothalamus and the BNST are also important for another set of sexually dimorphic behaviors in females. Nursing rodents are good mothers, building a nest for their litter, crouching over the pups to keep them warm, and returning the pups to the nest when they happen to crawl away. Surgical lesioning of either the preoptic region or the BNST abolishes these maternal behaviors.

Studies of these behaviors have shed light on variations among individual females and how these differences exert lifelong effects on behavior of the offspring. Female lab rats exhibit distinct, stable forms of maternal care: Some lick and groom (LG) their pups frequently (high-LG mothers), whereas others lick and groom less frequently (low-LG mothers). Female offspring of high-LG mothers display high-LG activity when they themselves become mothers compared to female offspring of low-LG mothers (Figure 58–10). Moreover, pups of high-LG mothers show less anxiety-like behaviors in stressful conditions than do the pups of low-LG mothers.

These results suggested that levels of licking and grooming behavior and stress responses are genetically determined. However, studies by Michael Meaney and

his colleagues provide an alternative explanation. When female rat pups are transferred from their mother to a foster mother at birth, their maternal behavior and stress responses as adults resemble those of their foster mother rather than those of their biological mother. Thus experience in infancy can lead to lifelong behavioral patterns. Because these patterns impact maternal behavior, their influence can endure over many generations.

How does brief and early experience lead to such long-lasting changes? One mechanism involves a covalent modification of the genome. Stress responses are coordinated by glucocorticoids acting on glucocorticoid receptors in the hippocampus. Throughout life tactile stimulation, including grooming, leads to transcriptional activation of the glucocorticoid receptor gene, which ultimately leads to reduced release of hypothalamic hormones that trigger stress responses. Tactile stimulation during early life also regulates the glucocorticoid receptor gene in a second way. A key site in the glucocorticoid receptor gene is methylated by the enzyme DNA methyltransferase, leading to gene inactivation. Initially gene methylation occurs in all pups, but pups reared by high-LG mothers are selectively demethylated. Thus in animals reared by high-LG mothers the effects of adult experience are potentiated. This is an example of epigenetic modification by which genes can be turned on or off more or less permanently. These animals exhibit blunted behavioral responses to stressful stimuli later in life.

What are the biological links between early experience and behavioral variation? A peptide hormone, oxytocin, plays a major role. Classical work showed that oxytocin regulates provision of milk by the mother, which occurs via reflex ejection in response to suckling (milk let-down). Oxytocin is synthesized by neurons in the hypothalamus and released into the general circulation through their projections in the posterior pituitary. It elicits smooth muscle contraction in the mammary gland, resulting in milk ejection. Oxytocin release from the pituitary is controlled by suckling, which provides a sensory stimulus that is conveyed to the hypothalamus by spinal afferent nerves.

Oxytocin and a related polypeptide hormone vasopressin also play important roles in regulating maternal bonding and other social behaviors (see Chapter 3). In these cases experience appears to modulate behaviors by affecting both release of oxytocin and levels of the oxytocin receptor in specific brain areas. In both rats and voles individual differences in the care females provide their offspring correlate with variations in oxytocin receptor level in specific brain areas. Especially noteworthy is that oxytocin receptor levels in

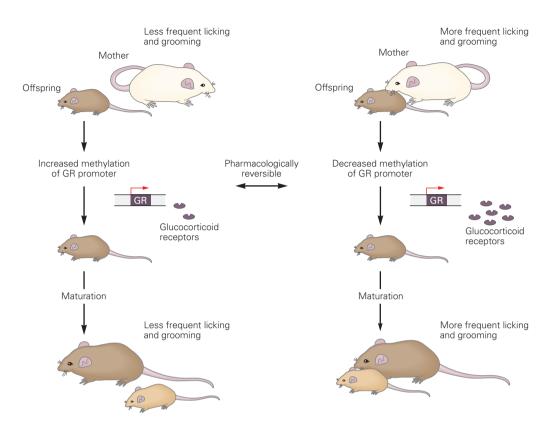

Figure 58–10 The regulation of maternal behavior by past social experience. In a common lab rat strain mothers lick and groom their pups at low or high frequencies, resulting in distinct epigenetic modifications at the glucocorticoid receptor (GR) promoter. Mothers that lick and groom at high frequency raise progeny with low levels of DNA methylation at the GR promoter, resulting in higher levels of GR expression in the hippocampus. Females raised by these mothers exhibit higher frequencies of licking and grooming behavior with their own

pups. Mothers that lick and groom at low frequency raise progeny with high DNA methylation levels at the GR promoter and lower levels of hippocampal GR expression. Females nursed by these mothers subsequently exhibit similar low levels of licking and grooming of their pups. Pharmacological reversal of the epigenetic modifications at the GR promoter results in a corresponding change in both GR expression and maternal behavior. (Modified, with permission, from Sapolsky 2004.)

several regions are higher in female offspring reared by high-LG mothers than in female progeny of low LG-mothers. Thus sensory stimulation may affect activity of the oxytocin and vasopressin systems, which in turn regulate maternal and other social behaviors.

These experiments suggest powerful mechanisms by which early experience can influence later behavior. Are they applicable to humans? Two recent observations suggest they are. First, as discussed in Chapter 56, children raised for lengthy periods in orphanages with little individual care have long-lasting defects in a variety of social behaviors. Even years after placement in foster homes these children have, on average, lower levels of oxytocin and vasopressin in their serum than children raised with biological parents. Second, people who have suffered abuse as children often grow up

to be poor parents. Postmortem studies have shown that adults who had been abused as children exhibited greater promoter methylation of their glucocorticoid receptor genes than adults in control populations. Although these studies are new and require replication, they provide tantalizing hints at the biological mechanisms that underlie the lifelong effects of early parental care.

Sexual Dimorphism in the Human Brain May Correlate with Gender Identity and Sexual Orientation

Are structural differences between the brains of male and female mammals also present in humans and, if so, might they be functionally important? Early studies revealed that a few structures are markedly larger in men: Onuf's nucleus in the spinal cord, the homolog of the spinal nucleus of the bulbocavernosus in rodents (Figure 58–7); the BNST, implicated in rodent mating behavior; and the interstitial nucleus of the anterior

hypothalamus 3 (INAH3), related to the rodent SDN-POA discussed earlier (Figure 58–11).

Advances in high-resolution magnetic resonance imaging (MRI) and genetic technology have uncovered more subtle structural and molecular dimorphisms in the central nervous system. For example, structures

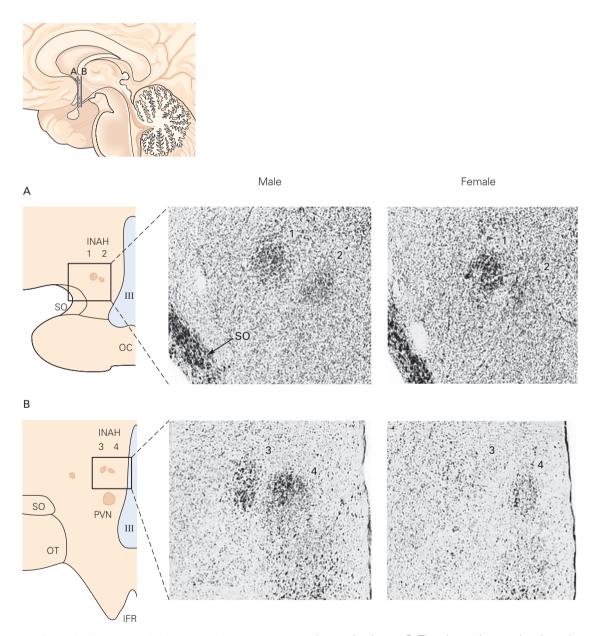

Figure 58–11 Sexual dimorphism in the interstitial nucleus of the anterior hypothalamus (INAH) 3 in the human brain. The human hypothalamus contains four small, discrete neuronal clusters, INAH1 through INAH4. While INAH1, INAH2, and INAH4 appear similar in men and women, INAH3 is significantly larger in men. The section in part A is 0.8 mm anterior to

the section in part B. The photomicrographs show these nuclei in adult male and female brains. (IFR, infundibular recess; III, third ventricle; OC, optic chiasm; OT, optic tract; PVN, paraventricular nucleus; SO, supraoptic nucleus.) (Reproduced, with permission, from Gorski 1988.)

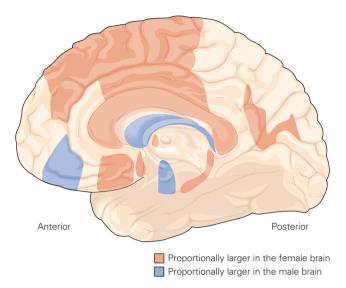

Figure 58–12 Sexual dimorphism is widespread in the adult human brain. A magnetic resonance imaging (MRI) study measured the volume of many brain regions in adult men and women. The volume of each region was normalized to the size of the cerebrum for both sexes. Sex differences were significant in many regions, including several cortical areas that likely mediate cognitive functions. (Modified, with permission, from Cahill 2006.)

such as the fronto-orbital cortex and several gyri—including the precentral, superior frontal, and lingual gyri—occupy a significantly larger volume in adult women compared to a cohort of adult men (Figure 58–12). Moreover, the frontomedial cortex, amygdala, and angular gyrus volumes are larger in men compared to women. Thus there are likely to be many sexual dimorphisms in the human brain.

What remains unclear is how these dimorphisms arise and how they relate to behavior. They might arise early from the organizational effects of hormones, or later as a result of experience. Structural differences arising before or soon after birth could underlie behavioral differences, whereas structural differences that arise later in life might be results of dimorphic behaviors.

Answers to these questions are fairly clear in a few cases. For example, studies of the development of neural circuits responsible for penile erection and lactation in rodents translate readily to humans. In contrast, differences in cognitive function, sexual partner preference, and gender identity are poorly understood. Little progress has been made in relating sex differences in cognitive functions to structural differences in the brain, in part because the very existence of

cognitive differences remains a matter of controversy; if they exist at all, they are small and represent differences in means between highly variable male and female populations. On the other hand several lines of evidence have connected clear differences in gender identity and sexual orientation to dimorphisms in the brain.

Early insight into this issue came from observation of people with single-gene mutations that dissociate anatomical sex from gonadal and chromosomal sex, such as CAIS, CAH, and 5α-reductase deficiency (see Table 58–1). For example, girls with CAH experience an excess of testosterone during fetal life; the disorder is generally diagnosed at birth and corrected. Nevertheless, the early exposure to androgens is correlated with subsequent changes in gender-related behaviors. On average, girls with CAH tend to exhibit toy preferences and play typical of boys of equivalent age. There is also a small but significant increase in the incidence of homosexual and bisexual orientation in females treated for CAH as children, and a significant proportion of these females also express the desire to live as men, consistent with a change in gender identity. These findings suggest that early organizational effects of steroids affect gender-specific behaviors independent of chromosomal and anatomical sex.

In 5α-reductase II deficiency and CAIS many of the afflicted males show feminized external genitalia and are mistakenly raised as females until puberty. Thereafter their histories diverge. In 5α -reductase II deficiency the symptoms arise from a defect in testosterone processing largely confined to the developing external genitalia. At puberty a large increase in circulating testosterone virilizes the body hair, musculature, and most dramatically, the external genitalia. At this stage many but not all patients choose to adopt a male gender. In CAIS, in contrast, defects arise from a bodywide defect in the androgen receptor. These patients commonly seek medical advice after they fail to menstruate at puberty. Concordant with their feminized external phenotype, most CAIS patients have a female gender identity and a sexual preference for men. They opt for surgical removal of the testes and hormonal supplementation appropriate for females.

What accounts for the different outcomes? Among many possibilities, one is that the dramatic change in behavior in 5α-reductase II patients at puberty results from the effects of testosterone acting on the brain. In CAIS patients these effects do not occur because androgen receptors are absent from the brain. Clearly, however, this explanation does not rule out social and cultural upbringing as important factors in determining gender identity and sexual orientation.

A second set of studies probing the biology of sexual orientation assessed responses to pheromones. Pheromone perception in humans is quite different from that of mice, and is likely a less important sense. Humans do not have a functional VNO, and most of the genes implicated in pheromone reception in mice, such as *trpc2* and those encoding VNO receptors, are absent (or nonfunctional pseudogenes) in the human genome. To the extent that humans do sense pheromones they appear to use the main olfactory epithelium and bulb. Chemicals that appear to be human pheromones include androstadienone (AND), an odorous androgenic metabolite, and estratetraenol (EST), an odorous estrogenic metabolite.

AND is present at 10-fold higher concentrations in male sweat compared to female sweat, whereas EST is present in the urine of pregnant women. Both compounds can produce sexual arousal, AND in heterosexual women and EST in heterosexual men, even at concentrations so low that there is no conscious olfactory perception.

Brain areas activated by AND and EST have been identified by positron emission tomography (PET) imaging. When AND is presented, certain hypothalamic nuclei are activated in heterosexual women but not heterosexual men, whereas when EST is presented, adjacent regions containing clusters of nuclei are activated in men but not women (Figure 58–13A).

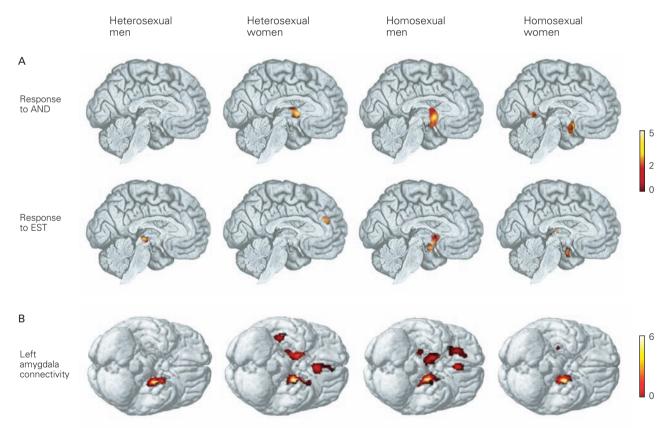

Figure 58–13 Some sexually dimorphic patterns of olfactory activation in the brain correlate with sexual orientation.

A. Positron emission tomography (PET) imaging was used to identify brain regions that were activated when subjects sniffed androstadienone (AND) or estratetraenol (EST) compared to nonodorous air. AND activated several hypothalamic centers in the brains of heterosexual women but not men, whereas EST activated several hypothalamic centers in heterosexual males but not females. Patterns of activation in the hypothalamus of homosexual men were similar to that of heterosexual women in response to AND, while similar patterns of activation were found in heterosexual men and homosexual women in response to EST. The color calibration on the right shows the level of putative

neural activity. Because the same brain regions were selected to compare the figure does not illustrate maximal activation for each condition. (Modified, with permission, from Berglund, Lindstrom, and Savic 2006; Savic, Berglund, and Lindstrom 2005.)

B. Heterosexual and homosexual subjects were scanned while breathing unscented air, and a measure of covariance was used to estimate connectivity among regions. In heterosexual women and homosexual men the left amygdala was strongly connected to the right amygdala, whereas connectivity remained local in heterosexual men and homosexual women. Because the same brain regions were selected to compare, the figure does not illustrate maximal activation for each condition. (Modified, with permission, from Savic and Lindstrom 2008.)

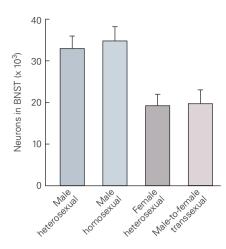

Figure 58–14 Sexual dimorphism in the human bed nucleus of the stria terminalis. The nucleus (BNST) has significantly more neurons in men compared to women regardless of male sexual orientation. Similar to women, male-to-female transsexuals have fewer neurons than men. In the one female-to-male transsexual brain available for postmortem analysis (not shown in the bar graph), the number of neurons is well within the normal range for men. (Modified, with permission, from Kruijver et al. 2000.)

In homosexual men and women there is a reversal of hypothalamic activation: AND but not EST activates hypothalamic centers in homosexual men, and conversely EST but not AND activates those areas in lesbian women. Heterosexual and homosexual brains therefore appear to process olfactory sensory information in different ways.

Do sexually dimorphic structures in homosexual brains correlate with anatomical sex or sexual orientation? Imaging studies have provided support for the view that the brains of homosexual men resemble those of heterosexual woman, and that the brains of homosexual women resemble those of heterosexual men (Figure 58–13B). Moreover, the volume of the sexually dimorphic BNST is small in male-to-female transsexuals compared to men, whereas female-to-male transsexuals appear to have a larger BNST compared to women (Figure 58-14). In these transgender individuals it remains possible that the structural dimorphism is a consequence rather than a cause of gender identity or sexual orientation. But they do raise the possibility that homosexual men and women are exposed prenatally to hormonal or other stimuli similar to those experienced by the other sex.

If prenatal influences do lead to dissociation of sex from gender, are those influences genetic? Other than the rare syndromes described earlier, attempts to find genetic bases for sexual orientation or gender identity have not been productive. Claimed genetic contributions are small and claims of associations with specific genomic loci have not been replicated. Thus, while the current weight of evidence favors some contribution of early, even prenatal, factors in these processes, their cause and relative weight remain unknown.

An Overall View

In most mammals, including humans, the sex determination pathway directs the differentiation of the testes in males and ovaries in females. The *SRY* gene on the Y chromosome is a master regulator that overrides a default female pathway to initiate formation of male gonads. The gonads then produce hormones that organize further differentiation of the body.

Of particular importance for generation of differences in the brain are the steroid hormones, including testosterone, estrogens, and progesterone. Again, the female pathway is often the default mode of differentiation, and at least during early life it is the absence of steroid hormones that permits feminization of brain and behavior to proceed. In many cases the underlying cellular phenomena resemble those that occur widely during normal development, such as apoptosis, neurite extension, synapse formation, and branch retraction. In sexually dimorphic structures these universal processes are brought under the control of sex steroids, so they occur to different extents in males and females. The effects of sex steroids are not confined to these irreversible organizational events during development; they also act in adult life to shape the behavioral repertoire of both sexes.

The link between sex differences in neuronal populations and behavior has been well established for behavioral responses such as erectile function and song production. Recent studies also provide insight into how individual variations in early experience are translated into adult variations in maternal behaviors. By contrast, we are only beginning to delineate the neural pathways underlying more complicated sexually dimorphic behaviors.

We do not yet understand how the nervous system generates various gender-related behaviors such as sexual orientation and gender identity. Here the relative contributions of genetic determinants and social experience remain to be determined. With advances in imaging and genetics, however, we are now poised to start linking specific neural pathways with sexually

dimorphic complex social behaviors. These studies have the potential to yield insight into fundamental aspects of human nature such as our sexuality and the basis of many of our social interactions.

The Aging Brain

The Structure and Function of the Brain Change with Age Cognitive Decline Is Dramatic in a Small Percentage of the Elderly

Alzheimer Disease Is the Most Common Senile Dementia

The Brain in Alzheimer Disease Is Altered by Atrophy, Amyloid Plaques, and Neurofibrillary Tangles

Amyloid Plaques Contain Toxic Peptides That Contribute to Alzheimer Pathology

Neurofibrillary Tangles Contain Microtubule-Associated Proteins

Risk Factors for Alzheimer Disease Have Been Identified

Alzheimer Disease Can Be Diagnosed Well but Available Treatments Are Poor

Overall View

The average life span in the United States in 1900 was about 50 years. Today it is approximately 76 years for men and 81 for women (Figure 59–1), and is higher still in 30 other countries. These increases result largely from a reduction in infant mortality, the development of vaccines and antibiotics, better nutrition, improved public health measures, and advances in the treatment and prevention of heart disease and stroke. Because of increased life expectancy, along with the large cohort of "baby boomers" born after World War II, the elderly are the most rapidly growing segment of the U.S. population.

Increased longevity is a double-edged sword: Agerelated cognitive alterations are increasingly prevalent. Their extent varies widely among individuals. For many, the alterations are mild and have relatively little

impact on the quality of life—the momentary lapses we jokingly call "senior moments." Other cognitive impairments, although not debilitating, are troubling enough to hinder the ability of the elderly to manage their lives independently. At the far extreme are the severe dementias, which rob the elderly of memory and reasoning. Of these, Alzheimer disease is the most prevalent.

As the population ages, research on age-related changes in the brain has become a more prominent area of focus for neuroscientists, neurologists, and psychologists. The main aim of research on aging has been to find treatments for Alzheimer disease and other dementias, but it is also important to understand the normal process of cognitive decline with age. After all, age is the greatest susceptibility factor for a wide variety of neurodegenerative disorders. Understanding what happens to our brains as we age may not only improve the quality of life for the general population but may also provide clues that will eventually help us vanquish seemingly unrelated pathological changes.

With this in mind, we begin this chapter with a consideration of how the normal brain ages. We then proceed to consider the broad range of pathological changes in cognition, and finally focus on Alzheimer disease, the most common cause of severe memory loss and intellectual deterioration in the elderly.

The Structure and Function of the Brain Change with Age

As we grow old our bodies change—our hair thins, our skin wrinkles, and our joints creak. It is no surprise

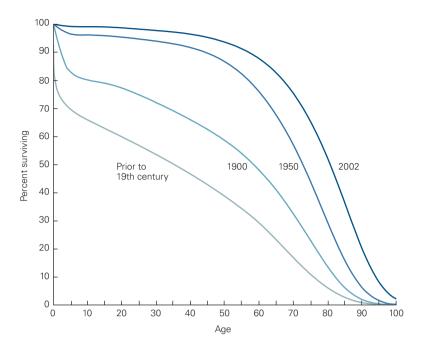

Figure 59–1 Human life span is increasing. Changes in human longevity illustrate the rapid extension in life span that has occurred in the United States over the past 100 years. (Modified, with permission, from Strehler 1975; Arias 2004.)

then that our brain also changes. Indeed, many of the behavioral alterations that occur with age affect almost everyone, providing evidence of underlying alterations in the nervous system.

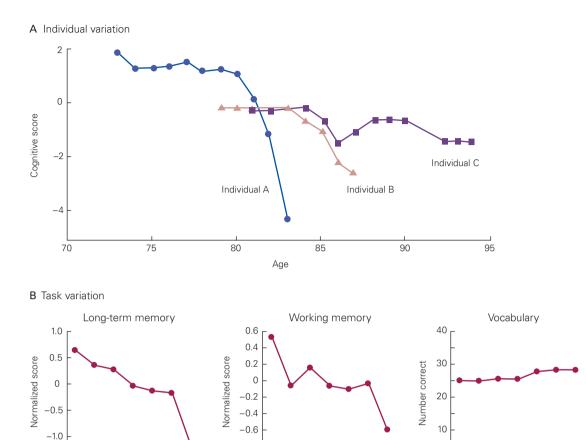

For example, motor skills decline in the elderly. The posture of an old person is less erect than that of a young adult. Gait is slower and stride length is shorter. Postural reflexes are often sluggish, making individuals more susceptible to loss of balance. Although muscles weaken and bones become more brittle, these motor abnormalities result in large part from subtle processes that involve the peripheral and central nervous systems. Sleep patterns also change with age: Older people sleep less and wake more frequently. Mental functions ascribed to the forebrain, such as memory and problem-solving abilities, also decline.

Age-related declines in mental abilities are highly variable. First, there are considerable differences in the rate and severity of cognitive decline among individuals (Figure 59–2A). Although most people experience a gradual decline in mental agility, for some the decline is rapid, whereas others retain their cognitive powers throughout life. Giuseppe Verdi, Eleanor Roosevelt, and Pablo Picasso are well-known members of this latter, unusual category. Titian continued to paint masterpieces in his late 80s, and Sophocles is said to have written *Oedipus at Colonus* in his 92nd year. The rarity of completely preserved function suggests that its retention may reflect special properties in the life

experiences or genes of these people. Accordingly, there has been great interest in studying rare individuals who retain nearly intact cognition into their tenth or even eleventh decade. These so-called "centenarians" may provide insight into environmental or genetic factors that protect against normal age-related cognitive decline or that protect against the more devastating pathological descent into dementia. For the moment, however, no such factors have been found.

Second, when data from many individuals are averaged, it is clear that some cognitive capacities decline significantly with age while others are largely spared (Figure 59–2B). For example, working and long-term memories, visuospatial abilities (measured by arranging blocks into a design or drawing a three-dimensional figure), and verbal fluency (as measured by rapid naming of objects or naming as many words as possible that start with a specific letter of the alphabet) usually decline with old age. On the other hand, measures of vocabulary, information, and comprehension often show minimal decline in normal individuals well into the 80s.

Age-related alterations in memory, motor activity, mood, sleep pattern, appetite, and neuroendocrine function result from alterations in the structure and function of the brain. Even the healthiest 80-year-old brain does not look like its 20-year-old self. Elderly people exhibit mild shrinkage in the volume of the brain and a loss in brain weight, as well as enlargement of the ventricles (Figure 59–3A). The decreases

in brain weight average 0.2% per year from college age onward, and about 0.5% per year in the 70s. One might imagine that these changes result from death of neurons, and indeed some neurons are lost with age. For example, 25% or more of the motor neurons that innervate skeletal muscles die in generally healthy elderly individuals. This loss contributes to sarcopenia, the muscle weakness and atrophy that can be a serious clinical problem in the elderly.

In general, however, there is minimal neuronal loss in most parts of the brain, so brain shrinkage must arise from other factors. Indeed, analysis of the brain of humans and experimental animals reveals structural alterations in both neurons and glia. Myelin is

fragmented and lost, leading to a decline in the integrity of white matter. At the same time, the density of the dendritic arbors of cortical and other neurons decreases, resulting in shrinkage of neuropil. In addition, levels of enzymes that synthesize some neurotransmitters, such as dopamine, norepinephrine, and acetylcholine, decrease with age, presumably resulting in functional defects in synapses that use these transmitters. Moreover, synapse structure is clearly aberrant, at least at the neuromuscular junction (Figure 59–4), raising the possibility that structural changes may also lead to functional deficits at central synapses. Finally, the number of synapses in the neocortex and many other regions of the brain declines (Figure 59–5).

These cellular changes lead to alterations in the integrity of the neural circuits that mediate our mental activities. Loss of synapses along with impairment in function of remaining synapses are thought to be important contributors to age-related cognitive decline. Changes in white matter are widespread but are especially notable in the prefrontal and temporal cortex. They may underlie alterations in executive functions and the ability to focus attention and to encode and store memory, functions that are localized in frontal-striatal systems and the temporal lobes. The loss of white matter may also help explain the recent finding that the elderly brain is less able to support synchronization of activity in widely separated areas that normally work together to carry out complex

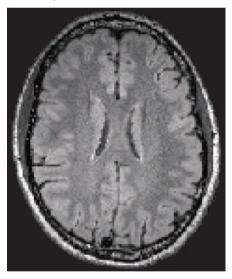

mental activities. Disruption of these large-scale networks could be an important cause of cognitive decline.

It was long thought that aging resulted from progressive deterioration of cells and tissues due to accumulated genetic damage or toxic waste products. In support of this idea, mitotic cells removed from animals and placed in a tissue culture dish divide only for a limited number of times before they age and die. This view of "preordained" aging has changed radically over the past decade, primarily as a result of studies in model organisms in which mutations that significantly extend life span have been found (Figure 59–6).

These dramatic discoveries establish that the aging process is under active genetic control. One such regulatory pathway that has been characterized includes

Valdez.)

insulin and insulin-like growth factors, their receptors, and the signaling programs they activate. Disruption of these genes leads to increased resistance of cells to lethal oxidative damage. Presumably, the normal forms of these genes benefit the organism during the

reproductive period and have therefore been selected by evolution. Their deleterious effects on longevity, once the animals are past reproductive age, may be an unfortunate side effect about which evolution cares little.

Figure 59–5 Age-related changes in synaptic density. Cognitive capacity during early development is accompanied by a marked increase in synapse density in different regions of the cerebral cortex. Developmental landmarks through age 10 months are indicated. The density of cortical synapses declines with age. (Adapted, with permission, from P. Huttenlocher.)

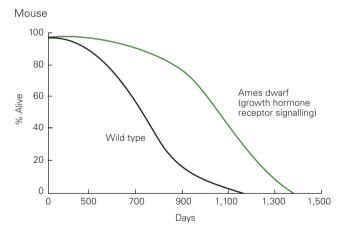

Figure 59–6 Life span can be increased through genetic mutation. Genetic mutations in specific receptors and signaling proteins markedly enhance life span in mutant strains of the worm, fly, and mouse, indicating that genetic regulatory mechanisms affect aging and life span. (Top reproduced, with permission, from Hekimi 2003; middle reproduced, with permission, from Yi 1998; bottom reproduced with permission, from Brown-Borg 1996.)

These findings have two major implications for understanding how aging affects the nervous system. First, the biochemical mechanisms that lead to, or protect from, the ravages of age are likely to underlie the changes in neurons that lead to cognitive decline. Research to explore this link between cellular change and cognitive functioning is now underway in model organisms. Second, and perhaps more excitingly, research on model organisms is leading to strategies for extending life span or health span (the period during which one remains generally healthy) by pharmacological intervention in the pathways uncovered by genetic studies.

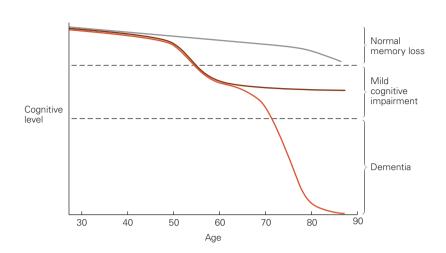

For example, the best-validated environmental intervention for extending life span in organisms ranging from yeast to worms to primates is caloric restriction, a strategy unlikely to be broadly acceptable to people. However, it appears that caloric restriction acts through genes in the insulin pathway mentioned above, and may involve a set of enzymes called sirtuins. The sirtuins are activated by a compound called resveratrol, originally isolated from red wine, a longevity-promoting beverage. Resveratrol, in turn, retards some aspects of aging, including cognitive measures, when administered to mice. While it is unlikely that resveratrol will serve as a fountain of youth in humans, it nevertheless exemplifies the new chemistries that are currently under consideration. These chemical strategies use model organisms to explore not only the positive factors that lead to aging but also the inhibitory constraints that prevent model organisms and presumably humans from achieving their full life span in a reasonably healthy state.

Cognitive Decline Is Dramatic in a Small Percentage of the Elderly

In most people age-related cognitive changes do not seriously compromise the quality of life. In a subset of elderly people, however, cognitive decline reaches a level that can be viewed as pathological. At the lesser end of the pathological range is a constellation of changes known as mild cognitive impairment, or MCI. This syndrome is characterized by memory impairments that may be alarming to the individual but are not serious enough to affect daily life; general cognition remains intact.

Owing to its subtlety, MCI is difficult to diagnose, but longitudinal studies have convinced neurologists that it is a real condition. Approximately 15% of individuals diagnosed with MCI progress to Alzheimer disease within a few years of diagnosis, and an additional 50% of them will eventually succumb to Alzheimer disease.

Figure 59–7 Cognitive performance can vary widely with age. Normal age-related memory loss does not impair cognitive abilities. Mild cognitive impairment is accompanied by a gradual and modest loss of cognitive abilities. Dementia is accompanied by a severe and accelerating loss of cognitive performance. The distinction between mild cognitive impairment and dementia becomes apparent only after the initial decline in cognitive performance. (From the National Institute on Aging: http://www.nia.nih.gov/alzheimers/publication/part-2-what-happens-brain-ad/changing-brain-ad)

Conversely, some elderly people with MCI remain at a stable plateau for decades (Figure 59–7). There is currently intense interest in learning how to distinguish individuals who will progress to more severe difficulties from those who will age relatively normally.

More troubling are the age-related or senile dementias. Senile dementia is a clinical syndrome in the elderly that involves progressive impairment of memory as well as cognitive faculties such as language, problem solving, judgment, calculation, or attention. Dementia syndromes are associated with a variety of diseases. The most common, Alzheimer disease, is discussed in detail below. The second most common cause of dementia in the elderly is cerebrovascular disease, particularly strokes that lead to focal ischemia and consequent infarction in the brain.

Large lesions in the cortex are often associated with language disturbances (aphasia), hemipareses, or neglect syndromes, depending on which portions of the brain are compromised. Small infarctions in white matter or deeper structures of the brain, termed *lacunes*, also occur as a consequence of hypertension. In small numbers they may be asymptomatic, or they may contribute to the normal cognitive decline of aging or underlie certain cases of mild cognitive impairment that do not progress to Alzheimer disease. As vascular lesions increase in number and size, however, their impact becomes heightened; eventually they can lead to dementia.

Numerous other conditions that can lead to dementia include Parkinson disease, alcoholism, drug intoxications, infections such as AIDS and syphilis, brain tumors, vitamin deficiencies (notably lack of vitamin B_{12}), thyroid disease, and a variety of other metabolic disorders. In some patients schizophrenia or depression may mimic a dementia syndrome. Emil Kraepelin chose the term "dementia praecox" to highlight the

cognitive deficit in a disease that affects young people, a disease we now call schizophrenia. Although the clinical features of these dementias may resemble those of Alzheimer disease or cerebrovascular disease in some respects, the symptoms and tempo of dementia may vary, depending on the nature and site of the neurological abnormality. Because some dementias can be treated, it is important for the physician to probe the differential diagnoses of dementia with clinical history, examinations, and laboratory studies.

Alzheimer Disease Is the Most Common Senile Dementia

In 1901 Alois Alzheimer examined a middle-aged woman who had developed memory deficits and progressive loss of cognitive abilities. One of the first noticeable symptoms of this woman's illness was unprovoked suspicion of her husband's behavior. Her memory became increasingly impaired. She could no longer orient herself, even in her own home, and she hid objects in her apartment. At times she believed that people intended to murder her.

She was institutionalized in a psychiatric hospital and died less than five years after the onset of illness. Alzheimer performed an autopsy that disclosed specific alterations in the cerebral cortex, described below. The constellation of behavioral symptoms and physical alterations was subsequently given the name Alzheimer disease (AD).

The first case of the disease caught Alzheimer's attention because it occurred in middle age, but in general the disease afflicts the elderly. Most patients with AD exhibit the first clinical signs during their seventh decade. Early onset cases are often familial, and mutations have

been discovered in many of these patients, as we shall discuss below. Late-onset cases are sporadic, and their cause remains unknown.

In both the sporadic and familial forms of AD there is a remarkably selective defect in declarative memory. At first, language, strength, reflexes, and sensory abilities and motor skills are nearly normal. Gradually, however, memory is lost along with cognitive abilities such as problem solving, language, calculation, and visuospatial perception. Unsurprisingly, these cognitive losses lead to other behavioral alterations, and some patients develop psychotic symptoms, such as hallucinations and delusions. In all patients mental functions and activities of daily living progressively become impaired; in the late stages these individuals are mute, incontinent, and bedridden.

Alzheimer disease affects approximately oneeighth of people older than 65 years. Five million people in the United States now suffer from dementia. Because the number of elderly is increasing rapidly, the population at risk for AD is the fastest growing segment of our society (Figure 59–8). During the next 25 years the number of people with AD in the United States will triple, as will the cost of caring for patients no longer able to care for themselves. Thus, AD is one of society's major public health problems.

The Brain in Alzheimer Disease Is Altered by Atrophy, Amyloid Plaques, and Neurofibrillary Tangles

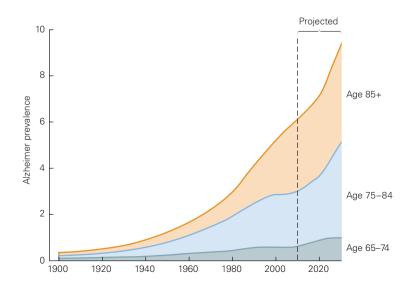

Alzheimer disease is characterized by three dramatic abnormalities of the brain, all of which Alzheimer described. First, the brain is atrophied, with narrowed gyri, widened sulci, reduced brain weight, and enlarged ventricles (Figure 59–9). These changes, seen in mild form in cognitively intact elderly people who die from other causes, are severe in advanced AD. Moreover, neuron death is widespread in AD, whereas in normal aged brains it is minimal. Thus AD is a neurodegenerative disease.

Second, sections of brains of AD patients obtained at autopsy reveal extracellular plaques of dense material called *amyloid*, large aggregates of fibrillar peptides arranged as sheets (Figure 59–10). Amyloid can be detected when stained with dyes such as Congo red, and is refractive when viewed in polarized light or when stained with thioflavin and viewed with fluorescence optics. The extracellular deposits of amyloid are surrounded by swollen axons and dendrites. These neuronal processes in turn are associated with processes of astrocytes and microglia (inflammatory cells). Amyloid plaques also occur in the walls of cerebral blood vessels in the Alzheimer brain.

Third, neurons that are affected but still alive have cytoskeletal abnormalities, the most dramatic of which is the accumulation of neurofibrillary tangles (Figure 59–10). These tangles are filamentous inclusions in the cell bodies and proximal dendrites that contain paired helical filaments and 15 nm straight filaments. Other cytoskeletal abnormalities occur in axons and terminals (dystrophic neurites) and dendrites (neuropil threads). Both types of lesions include intracellular paired helical filaments, suggesting that these fibrillar inclusions result from common mechanisms.

In AD these alterations do not occur uniformly throughout the brain, but rather affect specific regions. The entorhinal area, the hippocampus, the neocortex, and the nucleus basalis are especially vulnerable

Figure 59–8 Alzheimer disease is a growing public health problem. As the population ages, Alzheimer disease is expected to become increasingly prevalent (prevalence is measured in millions). (Adapted, with permission, from Brumback and Leech 1994, Herbert et al. 2003.)

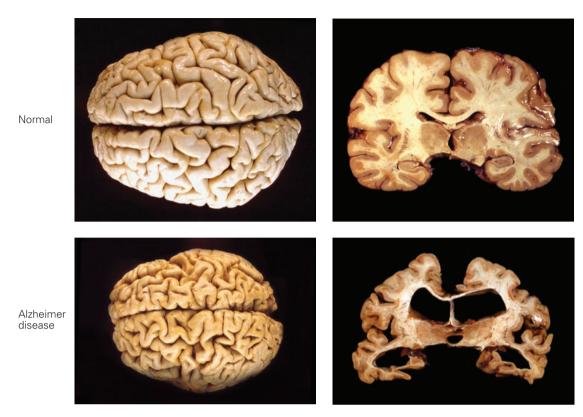

Figure 59–9 Overt pathological changes in the brain of individuals with Alzheimer disease. When compared to age-matched normal brains, the brain of an Alzheimer patient displays marked shrinkage and ventricular enlargement. (Whole

brain photos from P. Anderson, University of Alabama at Birmingham, Department of Pathology; brain slice photos from A. C. McKee; all reproduced with permission.)

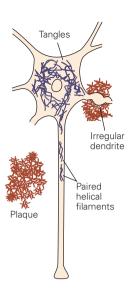

(Figure 59–11). Alterations in the entorhinal cortex and hippocampus are likely the structural underpinnings of problems with declarative memory that are the first symptoms of AD. These alterations contrast with those in frontostriatal circuits that correlate with age-related cognitive decline in normal subjects. Abnormalities in the basal forebrain cholinergic systems may contribute to cognitive difficulties and attention deficits that appear later in the progression of the disease. These anatomical differences, along with widespread neuronal death, argue against the idea, once prevalent, that AD is an extreme form of the normal aging processes.

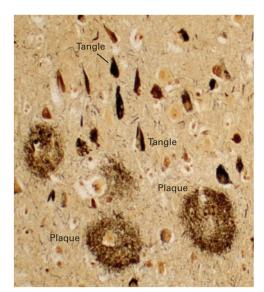

Amyloid Plaques Contain Toxic Peptides That Contribute to Alzheimer Pathology

To characterize amyloid plaques, George Glenner, Konrad Beyreuther, and their colleagues isolated the plaques by centrifugation, based on their low solubility, and determined some of their components. The principal constituent turned out to be a group of small peptides that together were named $A\beta$.

Two main forms of the peptide were found. The predominant peptide is 40 amino acids in length and the minor one 42 amino acids (the original 40 residues plus two additional amino acids at the carboxy terminal end). Biochemical studies showed that the A β 42 peptide nucleates more rapidly than A β 40 into amyloid fibrils. In individuals with AD, amyloid deposition begins with A β 42, while A β 40 accumulates later. Moreover, when applied to neurons in culture, the A β 42 peptide is more toxic than A β 40. These results implicate A β 42 as a key component of amyloid plaques.

In general, short peptides are formed by cleavage from a precursor protein, so researchers set out to isolate the protein from which A β was derived. The precursor was soon found and molecularly cloned, and named *amyloid precursor protein* or APP (Figure 59–12). APP is a large transmembrane glycoprotein that is present in the dendrites, cell bodies, and axons of many types of neurons as well as a variety of nonneuronal cells.

Neurofibrillary tangles

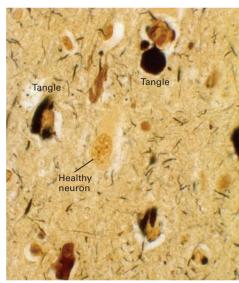

Figure 59–10 Plaques and tangles in the Alzheimer brain. A section of cerebral cortex from the brain of an individual with severe Alzheimer disease shows typical plaques and neurofibrillary tangles. (Images from James Goldman, reproduced with permission.)

Left: The diagram shows a neuron containing neurofibrillary tangles, composed of bundles of paired-helical filaments in the cell body and more paired helical filaments in the axon. Amyloid plaques are shown in the neuropil, one of them surrounding a dendrite, which displays an altered, swollen shape. Tangles are composed of abnormal polymers of hyperphosphorylated tau protein, and amyloid plaques are extracellular deposits of

polymers of the amyloid beta (A4) peptide.

Middle: A section of neocortex from a patient with Alzheimer disease has been treated with a silver stain. The tissue shows neuronal cell bodies containing neurofibrillary tangles and neuropil containing amyloid plaques.

Right: A higher magnification of the cortex shows neurofibrillary tangles in neuronal cell bodies and, in contrast, a healthy neuron without a tangle. Note the many thin silver-positive cell processes in the neuropil; these are neuronal processes that contain paired helical filaments.

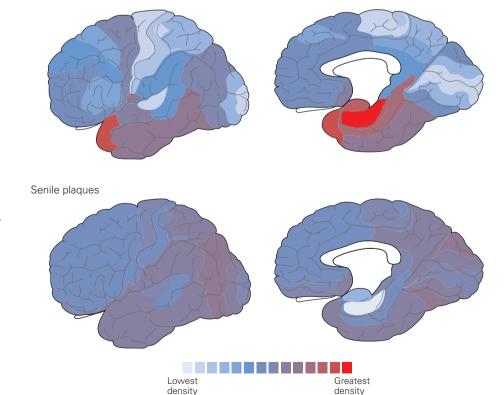

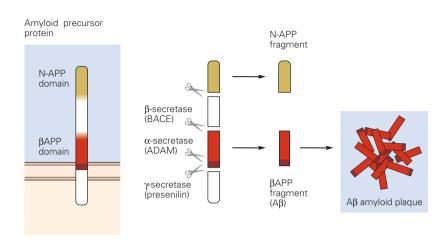

Figure 59–11 Neurofibrillary tangles and senile plaques are concentrated in different regions of the Alzheimer brain. Lateral and medial views of the cerebral hemispheres. (Adapted, with permission, from Arnold et al. 1991.)

Figure 59–12 Processing of the amyloid precursor protein. The amyloid precursor protein (APP) is a transmembrane protein of uncertain function. Through proteolytic cleavage it generates many distinct proteolytic fragments. Proteolytic cleavage by γ - and β -secretases generate an intracellular fragment, an $A\beta$ peptide, which can be 40 or 42 residues in length, and an amino-terminal fragment (N-APP) that may have distinct effects.

Despite intensive study, the normal functions of APP in the brain remain poorly understood.

Once APP was isolated it became possible to ask how it is processed to form AB peptides. The answer has turned out to be complex. Three proteolytic activities— α -, β -, and γ -secretases—cut APP into pieces. The β- and γ-secretases cleave APP to generate a soluble extracellular fragment that is released into the interstitial fluid, the Aβ peptides that include part of the transmembrane segment, and a cytosolic or intracellular fragment (Figure 59-12). The cleavage by y-secretase is unusual in that it occurs in a membrane-spanning portion of APP, a region long thought to be immune from hydrolysis because it is surrounded by lipids rather than water. In nonneuronal cells α -secretase cleaves APP in the middle of the Aβ sequence. This cleavage prevents the formation of Aβ peptides and helps explain why Aβ peptides are largely confined to the nervous system even though APP is present in neuronal and nonneuronal cells alike.

The enzymes that account for α -, β -, and γ -secretases have been isolated and characterized. α -Secretase is a member of a large family of extracellular proteases called *ADAM* (A Disintegrin and Metalloproteinase) that are responsible for degrading many components of the extracellular matrix. β -secretase, called β -site *APP cleaving enzyme 1* or BACE1, is a transmembrane protein in central neurons and concentrated in synaptic areas. Brain cells derived from mutant mice lacking BACE1 do not produce A β peptides, proving that BACE1 is indeed the neuronal β -secretase. γ -Secretase, the most complicated of the three, and the most recently isolated, is actually a multiprotein complex that cleaves several different transmembrane proteins.

As expected, given its peculiar ability to act within the membrane, γ -secretase itself includes membrane proteins. Two are called presenilin-1 and presenilin-2, reflecting their association with AD. Other components of the complex are nicastrin, Aph-1, and Pen-2, also transmembrane proteins.

Although the biochemical properties of A β and APP appeared interesting, the critical question remained: Are they causally related to the debilitating symptoms of AD? One might imagine that the disease is caused by A β accumulation, but A β might also form as a result of another pathological process or even be an innocuous correlate. Genetic evidence in humans and experimental animals has been critical in demonstrating that APP plays a central role in AD.

The first clue came from the observation that the APP gene lies on chromosome 21. Chromosome 21 is present in three copies (rather than the normal two) in people with Down syndrome. For this reason Down syndrome is also referred to as trisomy 21. Interestingly, it had long been known that most people with Down syndrome who live to the age of 40 develop AD. This association is consistent with the idea that excessive APP predisposes to AD.

More direct genetic evidence came from the analysis of patients with familial AD. Only a small number of cases of AD are familial, usually those in which onset occurs early, younger than age 60 years, and most of these are inherited as simple dominant mutations. As new methods of molecular cloning became available in the late 1980s, several groups began using them to identify the genes mutated in familial AD. Remarkably, the first three genes identified were those encoding APP, presenilin-1, and presenilin-2 (Figure 59–13). By

now many different mutations have been found in all three genes, and the majority of them influence cleavage of APP, increasing the production of A β peptides or the proportion of the more toxic A β 42 species.

Some APP mutations are amino acid substitutions flanking or within the A β region. Cells that express these mutant sequences secrete several-fold more A β peptide than cells expressing wild-type APP. Another APP mutation influences γ -secretase to selectively generate A β 42 rather than A β 40. Likewise, in most presenilin mutants the mutant γ -secretase has higher than normal activity or generates peptides with an increased ratio of A β 42 to A β 40. Thus mutants in the APP or presenilin genes do not lead to loss of the proteins but rather to increased production of A β 42.

These human studies offer compelling evidence that cleavage of APP plays a key causative role in at least some cases of familial, early-onset AD, and point to a role for A β 42. Because A β 42-rich amyloid plaques are a cardinal feature of the far larger group of patients with sporadic, late-onset AD, it is likely that APP cleavage is also involved in generating symptoms in this larger group.

Finally, genetic studies of mice have strengthened the case that APP cleavage contributes to AD. Transgenic mice that express relatively high levels of wildtype or mutant APP exhibit structural, physiological, and behavioral abnormalities associated with AD. Transgenic expression of mutant APP forms identical to those found in familial AD leads to appearance of amyloid plagues in the hippocampus and cortex, swollen neurites in proximity to AB deposits, decreased density of synaptic terminals in the forebrain, decrements in synaptic transmission, and degeneration of neurons. Moreover, these transgenic mice are deficient in tasks assessing spatial and episodic-like memory. Alterations are more severe in transgenic mice that express altered forms of both APP and presentilin-1. These lines of mice are invaluable tools for addressing mechanistic issues about the pathogenesis of AD and for testing potential therapies. Moreover, AD-like alterations in transgenic mice appear in a year or less rather than over decades, as in humans.

Given the strong evidence that APP cleavage is involved in the pathogenesis of AD, the next question is how the accumulation of cleavage products

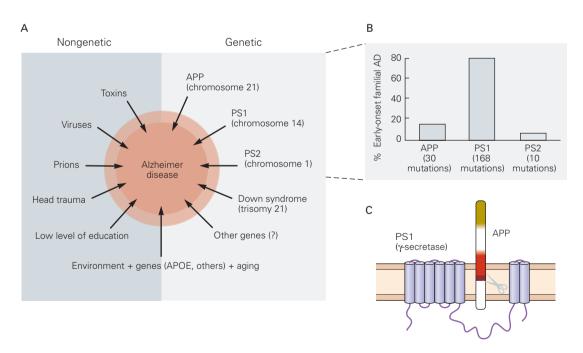

Figure 59–13 Environmental and genetic factors in Alzheimer disease.

A. Environmental and genetic factors. (ApoE, apolipoprotein E; APP, amyloid precursor protein; PS1, presenilin-1; PS2, presenilin-2.)

B. Specific genes involved in early-onset Alzheimer disease (AD).

C. Presenilin-1 is associated with APP proteins within the plasma membrane.

contributes to the symptoms. There are three sets of cleavage products: the secreted extracellular region (ectodomain), the A β peptide, and the cytoplasmic fragment. Greatest attention has been paid to the A β peptides, which were the first to be discovered. One view holds that A β in plaques, especially A β 42, poisons neurons in the vicinity, leading to synaptic dysfunction, degeneration of axon terminals, and eventually death of neurons.

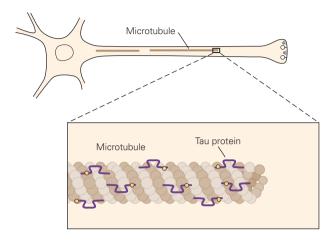

An alternative explanation is that aggregation of soluble forms of A β into plaques is the body's incompletely successful attempt to sequester toxic protein fragments. The A β peptides can bind to synaptic proteins and affect trafficking of postsynaptic neurotransmitter receptors, including glutamate receptors. Regulated trafficking of these receptors may be essential for forms of synaptic plasticity such as long-term depression and potentiation. As a result, memory defects in AD could involve interference by A β in plasticity. In turn, interference in synaptic function could lead to withdrawal and loss of synapses.

Involvement of Aβ peptides in AD does not mean that the other two cleavage products of APP, the cytoplasmic and extracellular fragments (Figure 59-12), have no role in AD. The cytoplasmic fragment can form a complex with other proteins, including Fe65, translocate to the nucleus, and influence transcription in ways that could be deleterious. Although there is little evidence that this mechanism contributes to AD, it is well established that Notch, a critical regulator of neurogenesis (see Chapter 53), is activated by γ -secretase cleavage and that its cleaved cytoplasmic fragment is transported to the nucleus, where it acts as a transcription factor. Likewise, the secreted extracellular fragment of APP appears to have toxic effects on nearby neurons. Thus it is possible that APP is a potent instigator of AD because the fragments generated from it by proteolytic cleavage damage neurons in different ways.

Neurofibrillary Tangles Contain Microtubule-Associated Proteins

Most research on the molecular and cellular basis of AD has focused on amyloid plaques but the neurofibrillary tangles have also been implicated in disease progression (Figure 59–10). Molecular analysis revealed that these abnormal inclusions in cell bodies and proximal dendrites contain aggregates of hyperphosphorylated isoforms of tau, a microtubule-binding protein that is normally soluble (Figure 59–14). Tau plays a key role in intracellular transport, particularly in axons, by binding to and stabilizing microtubules.

A Healthy neuron

B Alzheimer neuron

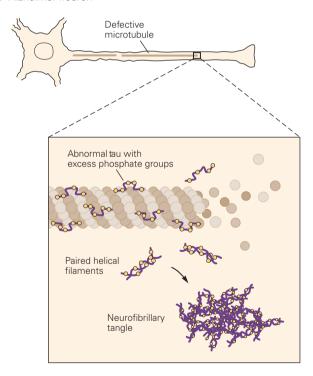

Figure 59–14 Neurofibrillary tangles contain mutant tau proteins.

A. In healthy neurons tau protein associates with normal microtubules but not paired helical filaments, and contributes to the structural integrity of the neuron.

B. In a diseased neuron the tau protein becomes hyperphosphorylated. As a consequence, phosphorylated tau loses its association with normal microtubules, which begin to disassemble, and instead associates with paired helical filaments, which become sequestered in neurofibrillary tangles (NFT).

Impairments in axonal transport compromise synaptic stability, trophic support, and other interactions. Eventually, affected nerve cells die and the neurofibrillary tangles remain in the extracellular space as tombstones of the cells destroyed by disease.

Although tangles are a defining feature of AD, it remains unclear what role they, and the hyperphosphorylated tau of which they are made, play in the pathogenesis of the disease. Whereas mutations of APP and presenilin genes can lead to AD, no mutations of the tau gene have been found in familial AD. This difference leads some to view tangles as a consequence or correlate, but not a cause, of AD symptoms.

Other observations suggest a more causal relationship. First, filamentous deposits of hyperphosphorylated tau are seen in a variety of neurodegenerative disorders. Second, mutations in the tau gene have been found to underlie another form of inherited dementia, frontotemporal dementia with Parkinson disease type 17 (FTPD17), which shares some features with AD but lacks plaques. Third, symptoms of AD correlate better with the number and distribution of tangles than that of plaques seen in autopsy material. For example, tangles are usually first evident in neurons of the entorhinal cortex, the likely site of early memory disturbance, before plaques appear in this area.

For many years controversy has raged between those who believe that $A\beta$ is the main causal agent of AD and those who believe that tau-rich tangles play a major role. These advocates have been called "Baptists" and "Taoists," respectively. It now seems most likely that both $A\beta$ and tau are involved, and that pathology results from their combined effects. For example, transgenic mice that express both mutant APP and mutant tau develop more severe AD-like behavioral deficits than mice overexpressing either alone. Moreover, there appears to be interplay between plaques and tangles. Thus injection of Aβ42 into specific brain regions of transgenic mice that express a mutant tau protein increases the number of tangles in nearby neurons, and a manipulation that reduces the number and size of plaques leads to a decrease in levels of hyperphosphorylated tau. Thus, even if tangles are not sufficient to "cause" AD, they are likely to play a role in symptoms and disease progression.

Risk Factors for Alzheimer Disease Have Been Identified

A few individuals develop AD because they bear mutant alleles of the APP or presenilin genes, but in most cases no genetic or environmental causes are obvious. Can we, then, predict who will get AD?

The major risk factor is age. The disease is present in a vanishingly small fraction of people younger than age 60 (these being mostly familial cases), 1–3% of those between ages 60 and 70, 3–12% of those between ages 70 and 80, and 25–35% of those older than age 85. Thus one safe prediction is that elderly people are prime candidates for AD. However, this statistical association is of little therapeutic use because modern medicine can do nothing to slow the passage of time. There has therefore been intense interest in other factors that affect the incidence of AD.

The most significant genetic risk factor discovered to date in sporadic late-onset AD is an allele of the gene ApoE. The ApoE protein is the major carrier of cholesterol and other lipids in the blood. The gene is expressed as three alleles, ApoE2, ApoE3, and ApoE4, which differ from each other at only a few amino acids (Figure 59–15). People with the ApoE4 allele are at risk for AD. This allele is present in only a few percent of the general population but in 40-50% of those with AD. Put another way, carrying one ApoE4 allele increases by about fourfold one's chance of developing AD, compared to people who carry only ApoE2 or *ApoE3* alleles. The mechanism by which *ApoE4* predisposes one to AD is not known. Moreover, ApoE4 is a risk factor for several neurological diseases, including Parkinson disease and multiple sclerosis, so it may act in ways that do not involve APP or Aβ directly.

Alzheimer Disease Can Be Diagnosed Well but Available Treatments Are Poor

Diagnosing AD at its early stages is challenging as its initial symptoms are similar to the changes that are part of normal age-related cognitive decline. Until recently, even diagnosis of more advanced AD was difficult. In the 1970s diagnostic error rates were approximately 30%, as judged by the best objective measure: the detection of plaques and tangles at autopsy. Indeed, until biological and genetic research provided a deeper understanding of the pathology, it remained somewhat controversial whether AD was best viewed as a discrete disease or as one end of a continuum that passed from normal aging through mild cognitive impairment to dementia.

During the past few decades the situation has improved, largely because of three factors. First, protocols for physical, neurological, and neuropsychological examination have become more sophisticated and standardized. Second, increased knowledge of the structural changes revealed by magnetic resonance imaging (MRI) have helped in diagnosing AD at early

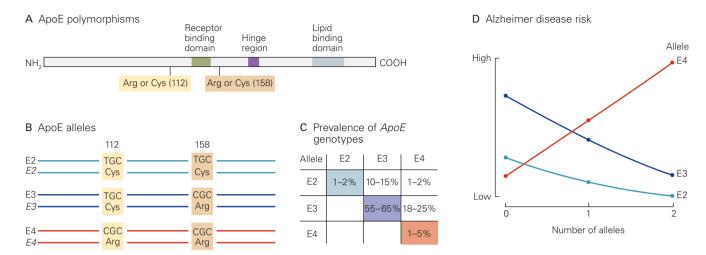

Figure 59–15 Polymorphisms in the *ApoE* gene are a prominent risk factor for Alzheimer disease.

A. Polymorphisms in the *ApoE* gene involve changes in amino acid sequence at two critical residues (112 and 158).

B. Changes in amino acid sequence in the three ApoE alleles.

C. Prevalence of ApoE genotypes in the general population.

D. ApoE alleles are risk factors for Alzheimer disease. Inheritance of one ApoE4 allele increases by about fourfold the probability of progressing to Alzheimer disease. Inheritance of the ApoE2 allele reduces the risk.

stages. For example, it is now possible to predict, with approximately 80% accuracy, which patients with mild cognitive impairment will proceed to AD based on the cortical thinning and ventricular enlargement visible by MRI. These imaging and diagnostic methods also assist in distinguishing dementia syndromes from each other and relating structural to functional defects. For example, early in a disease called *semantic dementia*, patients have difficulty naming objects, and MRI reveals atrophy of the temporal poles. In contrast, in AD initial difficulties center on memory, and MRI reveals initial alterations in the medial temporal cortex and hippocampus.

Third, and perhaps most promising, amyloid plaques can now be visualized by positron emission tomography (PET) using new compounds that avidly bind amyloid. The first of these, called *Pittsburgh compound B* (PIB), binds with high affinity to Aβ, and its radioactive form, labeled with short-lived isotopes of carbon or fluorine, is readily detected by PET (Figure 59–16). The availability of safe molecular markers of AD permits early stages of the disease to be studied, before clinical symptoms are present. Of equal importance, the ability to distinguish older adults with and without amyloid plaques permits, for the first time, detailed analyses of normal aging uncomplicated by confounding early-stage AD.

Improved diagnosis of AD is, of course, most useful if treatments are available that can halt or slow

its progression at an early stage. Here the news is not so good. At present there is no cure for Alzheimer disease. Present-day therapies focus on treating associated symptoms, such as depression, agitation, sleep disorders, hallucinations, and delusions. One of the principal targets is the cholinergic system in the basal forebrain, a region of the brain that is severely damaged in Alzheimer disease. Several strategies have been developed to influence this cholinergic system. Acetylcholinesterase inhibitors increase levels of acetylcholine by inhibiting its breakdown, and represent one of the few drugs approved by the FDA for treatment of AD. Unfortunately, these drugs exert, at best, a modest effect on cognitive functions and the activities of daily living. Likewise, addition of precursors of acetylcholine (choline, lecithin, etc) or cholinergic agonists have not proven effective.

On the other hand, recent increases in our understanding of the biological basis of AD have highlighted several promising new therapeutic targets, all of which are being explored intensively. One approach is to develop drugs that reduce the activity of the β - and γ -secretases that cleave APP to generate A β peptides and the associated soluble extracellular and intracellular fragments. In fact, decreasing either β - or γ -secretase levels in transgenic mice that overexpress mutant APP decreases both A β deposition and age-associated memory abnormalities in these models. Accordingly, pharmaceutical companies are trying to develop drugs that

will decrease levels of β - and γ -secretases in humans. An obstacle to this approach is that the secretases have other substrates in addition to APP, so decreasing their levels can have deleterious side effects. For example, one promising inhibitor of γ -secretase also decreased production of T and B cells of the immune system. As an alternative, it may be possible to find cleavage-inhibiting drugs that bind to critical sites on APP rather than to the secretases.

Other researchers are targeting the different proteins that have been implicated in AD: α -secretase, ApoE4, and tau. Because α -secretase cleaves in the middle of A β , it prevents A β accumulation. Researchers are exploring ways to increase α -secretase levels or activity. Conversely, ApoE4 predisposes to AD, whereas ApoE3 is innocuous or protective. Researchers are therefore seeking ways to convert the properties of ApoE4 into those of ApoE3, or to target the receptors through which it acts. Likewise, interventions that prevent hyperphosphorylation of tau could slow generation of neurofibrillary tangles, which appear to worsen neuronal health in a variety of neurodegenerative diseases.

Another approach is to decrease levels of $A\beta$ through immunological means. Immunization with $A\beta$, which leads to generation of antibodies of $A\beta$, and passive transfer of antibodies to $A\beta$ have been tested in transgenic mice models of Alzheimer disease. Both treatments reduce levels of $A\beta$ and plaques. The mechanisms of enhanced $A\beta$ clearance are not certain. Serum antibodies likely serve as a "sink" to extract low molecular weight $A\beta$ peptides from the brain into

the circulation, thus changing the equilibrium of $A\beta$ in different compartments and promoting removal of $A\beta$ from the brain. Alternatively, a small amount of $A\beta$ antibody could reach the brain, bind $A\beta$, and recruit microglia to enter the affected regions and remove $A\beta$. Whatever the mechanism, $A\beta$ immunotherapy in mice appears to reduce $A\beta$ levels (Figure 59–17) and thus attenuate the otherwise severe impact of amyloid plaque on learning and cognition. These findings suggest that immunotherapeutic strategies may be successful in AD patients.

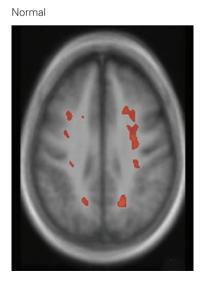

An Overall View

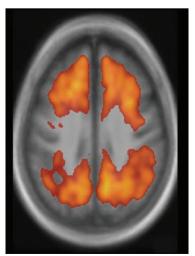

Aging affects the brain in many ways. Some changes are subtle, and the neurobiological basis of accompanying behavioral disturbances is unclear. Other problems are moderate, as in mild cognitive impairment (MCI). Some deficits are progressive and disabling as occurs in the various dementia syndromes. The most common dementia in the elderly is Alzheimer disease (AD), one of the most complex diseases in clinical medicine.

Alheimer disease is a common cause of morbidity and mortality in the elderly. In recent years there have been major advances in understanding this disease. Investigators have more accurately documented the relationship of MCI to early AD, identified genetic causes and risk factors, developed a variety of new diagnostic approaches that allow detection of amyloid plaques in living people, and clarified

Alzheimer disease

the ways in which the character, distributions, and stages of pathology are related to clinical signs. The mechanisms that lead to formation of plaques and tangles have begun to be delineated and studies of in vitro and in vivo models systems have led investigators to identification of potential new targets for treatment.

We are now on the threshold of implementing novel therapies based on an understanding of the neurobiology, neuropathology, biochemistry, and genetics of this illness. Moreover, a variety of tools, including biomarkers, brain imaging, and measures of $A\beta$ flux between brain and plasma compartments, are now being developed to

assess efficacies of treatments. Over the next few years it seems possible that these discoveries will lead to the rational design of new therapies that can be tested in animal models. With perseverance and luck, some of these approaches may be introduced into the clinic to benefit AD patients, for whom medicine has so far had very little to offer.

Wooden sculpture of the itinerant Buddhist monk Kūya. This portrait by the 13th century sculptor Kōshō shows the monk reciting the *nembutsu*, or praise of the Buddha, which in Japan takes the form of six characters. Kuya taught that focused recitation of the nembutsu would lead to rebirth in the Pure Land, a state of spiritual illumination. The six small Buddhas issuing from his mouth represent the six syllables of the spoken prayer. This portrayal shows remarkable complexity of representation, with pieces of wood carved in the shape of figurines, symbolizing discrete components of speech, which together represent language, its underlying concept, and in this case a means to spiritual enlightenment. (Reproduced, with permission from Rokuharamitsuji-temple, Kyoto, Japan.)

IX

Language, Thought, Affect, and Learning

OTOR AND SENSORY FUNCTIONS take up less than one-half of the cerebral cortex in humans. The rest of the cortex is occupied by the association areas, which coordinate events arising in the motor and sensory centers. Three association areas—the prefrontal, parietal-temporal-occipital, and limbic—are involved in cognitive behavior: speaking, thinking, feeling, perceiving, planning, learning, memory, and skilled movements.

Most of the early evidence relating cognitive functions to the association areas came from clinical studies of brain-damaged patients. Thus, the study of language in patients with aphasia yielded important information about how human mental processes are distributed in the two hemispheres of the brain and how they develop.

Genetic manipulation in experimental animals can now be used to evaluate the relative contribution of genes and learning to specific types of behavior. Even the highest cognitive abilities have a genetic component. Composing music is an excellent example. Music conforms to complex, unusually abstract rules that must be learned, yet clearly it has genetic components intertwined with its learned aspects. The great composer Johann Sebastian Bach had many children, five of whom were distinguished musicians and composers. His only grandson also was a composer and harpsichordist to the court of Prussia. In 1730, Bach proudly wrote that he was able to "put on a vocal and instrumental concert with my own family."

Much of today's neural science concerns cognitive neural science, a merger of neurophysiology, anatomy, developmental biology, cell and molecular biology, and cognitive psychology—a merger that has given rise to a new science of mind. Until two decades ago the study of higher mental function was approached in two complementary ways: through psychological observation and through invasive experimental physiology. In the first part of the 20th century, to avoid untestable concepts and hypotheses, psychology became rigidly concerned with behaviors defined strictly in terms of observable stimuli and responses. Orthodox behaviorists thought it unproductive to deal with consciousness, feeling, attention, or even motivation.

By concentrating only on observable actions, behaviorists asked: What can an organism do, and how does it do it? Indeed, careful quantitative analysis of stimuli and responses has contributed greatly to our understanding of the acquisition and use of "implicit" knowledge of perceptual and motor skills. However, humans and other higher animals also have "explicit" knowledge of facts and events. Thus we also need to ask: What does the animal know about the world, and how does it come to know it? How is that knowledge represented in the brain? And does explicit knowledge differ from implicit knowledge? Much perhaps most, knowledge is unconscious a great deal of the time. We need to know the nature of the unconscious processes, the systems that mediate them, and their influence on the nature of conscious mental activity. Finally, we need to know about the highest realms of conscious knowledge, the knowledge of oneself as an individual, a thinking and feeling human being.

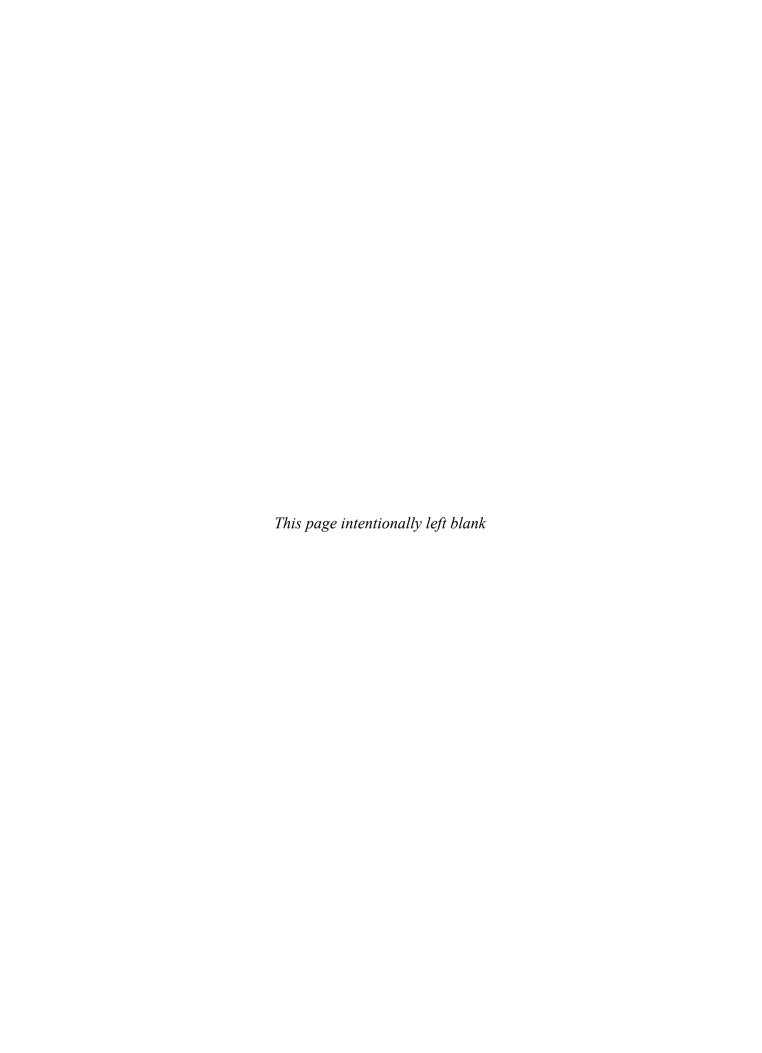

The modern effort to understand the neural mechanisms of higher mental functions began at the end of the 18th century when Franz Joseph Gall, a German neuroanatomist, proposed that particular mental functions are discretely localized in the brain. By the mid-19th century, clinical neurologists, who regarded their patients as "natural experiments" in brain function, studied brain lesions at autopsy to discover where particular brain functions were located. In 1861, Pierre Paul Broca, using evidence from the damaged brains of aphasic patients, convinced the scientific establishment that speech is controlled by a specific area of the left frontal lobe. Soon afterward the control of voluntary movement was localized, and the various primary sensory cortices for vision, audition, somatic sensation, and taste were delineated.

Neural science is only beginning to analyze the nature of the internal representations that cognitive psychologists have insisted intervenes between stimulus and response, and the very real dynamic unconscious mental processes studied by psychoanalysts—only now beginning to address the subjective sense of individuality, will, and purpose that is common to us all. In the past, ascribing a particular behavioral feature to a mental process that could not be directly observed meant that the process must be excluded from study because no reliable technique was available to examine brain function in the context of behavior. In Part IX, we show that because the nervous system and even its unconscious mental processes have become more accessible to behavioral experiments, internal representations of experience can be explored in a controlled manner.

A key concern of cognitive psychology and psychoanalysis is the relative importance of genetic and learned factors in forming a mental representation of the world. These disciplines can be strengthened by the insights into behavior that neuroscience now offers. The task for the years ahead is to produce a psychology still concerned with problems of mental representation, cognitive dynamics, and subjective states of mind but grounded firmly in empirical neural science.

The Classical Aphasias Have Not Implicated All Brain Areas Important for Language

An Overall View

ANGUAGE IS UNIQUELY HUMAN and arguably our greatest skill and our highest achievement. Despite its complexity, all typically developing children master it by the age of three. What causes this universal developmental phenomenon, and why are children so much better at acquiring a new language than adults? Once language is mastered, what brain systems are involved in language processing, and how does brain damage produce the various disorders of language known as the aphasias?

For centuries these questions about language and the brain have prompted vigorous debate among theorists. In the last decade, however, an explosion of information regarding language has taken us beyond the nature–nurture debates and beyond the standard view of specialized brain areas responsible for language. Two factors are largely responsible for this change.

First, functional brain imaging techniques such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), electroencephalography, and magnetoencephalography have allowed us to examine activation patterns in the brain while the subject carries out language tasks—naming objects

or actions, listening to sounds or words, or detecting grammatical anomalies. The results of these studies reveal a far more complex picture than the one first conceived of by Carl Wernicke in 1874, a picture in which multiple and relatively segregated brain systems cooperate functionally in language processing.

Second, behavioral and brain studies of language acquisition show that infants learn language in ways that had not been envisioned. Well before children produce their first words, they learn the sound patterns underlying the phonetic units, words, and phrase structure of the language they hear. Listening to language alters the infant brain early in development, and early language learning affects the brain for life. These new findings have led to a new view of language that encompasses its development, mature state, and dissolution in aphasia.

Humans are not the only species to communicate. Passerine birds attract mates with songs, bees code the distance and direction to honey by dancing, and monkeys signal a desire for sexual contact or fear at the approach of an enemy with coos and grunts. With language we accomplish all of the above and more. We use language to provide information and express our emotions, to comment on the past and future, and create fiction and poetry. Using sounds that have only an arbitrary association with the meanings they convey, we talk about anything and everything. No animal has a communication system that parallels human language either in form or in function. Language is the defining characteristic of humans, and living without it creates a totally different world, as patients with aphasia following a stroke experience so heartbreakingly.

Language Has Many Functional Levels: Phonemes, Morphemes, Words, and Sentences

What distinguishes language from other forms of communication? The key feature is a finite set of sounds that can be combined with infinite possibilities. This set of sounds or phonemes is used to create semantic units called morphemes. Each language has a distinctive set of phonemes and rules for combining them into morphemes and words. Words can be combined according to the rules of syntax into an infinite number of sentences.

Understanding language presents an interesting set of puzzles, one that even supercomputers have thus far not mastered. Computers even have difficulty with phonetic discrimination. For example, in English the sounds /r/ and /l/ differentiate the words *rock* and *lock*. In Japanese, however, this sound change does not

alter the meaning of a word as the /r/ and /l/ sounds are used interchangeably. Similarly, Spanish speakers distinguish between the words *pano* and *bano*, whereas English speakers treat the /p/ and /b/ sounds at the beginning of these words as the same sounds. Given that many languages use identical sounds, but group them differently, children must discover how sounds are grouped to make meaningful differences in their language.

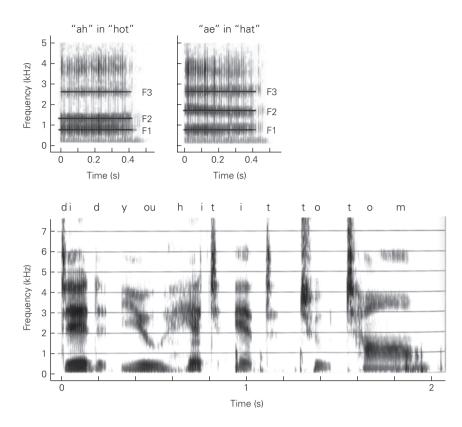

Phonetic units are sub-phonemic. As we have illustrated above with /r/ and /l/, they are both phonetic units but their phonemic status differs in English and Japanese. In English, the two are phonemically distinct, meaning that they change the meaning of a word. However, in Japanese /r/ and /l/ belong to the same phonemic category and are not distinct. Phonetic units are distinguished by subtle variations in vibrations of the vocal tract called formant frequencies (Figure 60–1). The patterns and timing of formant frequencies distinguish words that differ in only one phonetic unit, such as the words pat and bat. In normal speech, formant changes occur very rapidly, on the order of milliseconds. The auditory system has to track these rapid changes to distinguish semantically different sounds and understand speech. Identifying words in written language is easy because there are spaces between words. However, in speech there are no acoustic breaks between words. Thus speech requires a process that can detect words on the basis of something other than sounds bracketed by silence. Computers have a great deal of trouble recognizing words in the normal flow of speech.

Phonotactic rules specify how phonemes can be combined to form words. Both English and Polish use the phonemes /z/ and /b/, for example, but the combination zb is not allowed in English, whereas in Polish it is common (as in the name Zbigniew).

Morphemes are the smallest meaningful units of a language, best illustrated by prefixes and suffixes. In English, for example, the prefix un (meaning not) can be added to many adjectives to convey the opposite meaning (eg, unimportant). Suffixes often signal the tense or number of a word. For example, to pluralize in English we add s or es (pot becomes pots, bug becomes bugs, or box becomes boxes). To change the tense of a regular verb we add an ending to the word (eg, play can become plays, playing, and played). Irregular verbs do not follow the rule (eg, go becomes went rather than goed, and break becomes broke rather than breaked). Every language has a different set of rules for altering the tense and number of a word.

Finally, to create language, words have to be strung together. *Syntax* specifies word and phrase order for

Figure 60–1 Formant frequencies. Formants, shown here as a function of time in a spectrographic analysis of speech, are systematic variations in the concentration of energy at various frequencies, and represent resonances of the vocal tract. The formant patterns for two simple vowels ("ah" and "ae") spoken in isolation are distinguished by differences in formant 2 (F2). Formant patterns for the sentence "Did you hit it to Tom?" spoken slowly and clearly illustrate the rapid changes that underlie normal speech. (Adapted, with permission, from Kuhl 2000.)

a given language. In English, for example, sentences typically conform to a subject–verb–object order (eg, *He eats cake*), whereas in Japanese, it is typically subject–object–verb (eg, *Kare wa keeki o tabemasu*, literally, *He cake eats*). Languages have systematic differences in the order of larger constituents (noun phrases and verb phrases) of a sentence, and in the order of words within constituents, as illustrated by the difference between English and French noun phrases. In English adjectives precede the noun (eg, *a very intelligent man*), whereas in French most follow the noun (eg, *un homme très intelligent*).

Language Acquisition in Children Follows a Universal Pattern

Regardless of culture, all children initially exhibit universal patterns of speech perception and production that do not depend on the specific language children hear (Figure 60–2). By the end of the first year infants have learned through exposure to a specific language which phonetic units convey meaning in that language and recognize likely words, even though they do not yet understand those words. By 12 months of age

infants understand approximately 50 words and have begun to produce speech that resembles the native language. By the age of 3 years children know approximately 1,000 words (by adulthood 70,000), create long adult-like sentences, and can carry on a conversation.

In the last half of the 20th century debate on the nature and acquisition of language was ignited by a highly publicized exchange between a strong learning theorist and a strong nativist. In 1957 the behavioral psychologist B. F. Skinner proposed that language was acquired through learning. In his book Verbal Behavior Skinner argued that language, like all animal behavior, was a learned behavior that developed in children as a function of external reinforcement and careful parental shaping. By Skinner's account infants learn language as a rat learns to press a bar—through monitoring and management of reward contingencies. The nativist Noam Chomsky, writing a review of Verbal Behavior, took a very different position. Chomsky argued that traditional reinforcement learning has little to do with humans' abilities to acquire language. Instead, every individual has an innate "language faculty" that includes a universal grammar and a universal phonetics; exposure to a specific language triggers a "selection" process for one language.

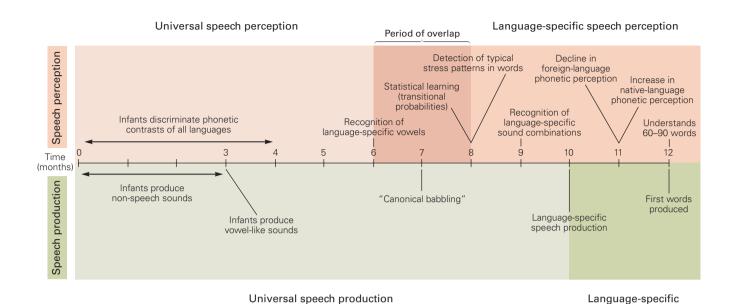

Figure 60–2 Language development progresses through a standard sequence in all children. Speech perception and production in children in various cultures initially follow a language-universal pattern. By the end of the first year

of life, language-specific patterns emerge. Speech perception becomes language-specific before speech production. (Adapted, with permission, from Doupe and Kuhl 1999.)

speech production

More recent studies of language acquisition in infants and children have clearly demonstrated that the kind of learning going on in infancy does not resemble that described by Skinner with its reliance on external shaping and reinforcement. However, a nativist account such as Chomsky's, in which the language the infant hears triggers a choice among innate options, also does not capture the process.

The "Universalist" Infant Becomes Linguistically Specialized by Age 1 Year

In the early 1970s psychologist Peter Eimas showed that infants were especially good at hearing the acoustic changes that distinguish phonetic units in the world's languages. He showed that infants could discern slight acoustic changes at the boundaries between phonetic categories, and that they could do this for phonetic units in languages they had never experienced. The phenomenon is called *categorical perception*; adults have this ability only for phonetic units in languages in which they are fluent. Japanese people, for example, find it very difficult to hear the distinction between the American English /r/ and /l/ sounds. Both are perceived as Japanese /r/, and, as we have seen, Japanese speakers use the two sounds interchangeably when producing words.

Categorical perception was originally thought to occur only in humans, but in 1975 cognitive neuroscientist Patricia Kuhl showed that it exists in nonhuman mammals such as chinchillas and monkeys. Since then many studies have confirmed this result (as well as species differences). The studies suggest that the evolution of phonetic units was strongly influenced by preexisting auditory structures and capacities. Infants' ability to hear all possible differences in speech prepares them to learn any language; at birth they are linguistic "universalists."

Right before the onset of first words, infants' ability to discriminate nonnative phonetic units rapidly declines. By the end of the first year, infants fail to discriminate phonetic changes that they successfully recognized 6 months earlier. At the same time, infants become significantly more adept at hearing nativelanguage phonetic distinctions. For example, when American and Japanese infants were tested between 6 and 12 months of age on the discrimination of the American English /r/ and /l/, American infants improved significantly between 8 and 10 months, whereas Japanese infants declined, suggesting that this is a sensitive period for phonetic learning.

Speech production develops simultaneously with speech perception (Figure 60–2). All infants, regardless of culture, produce sounds that are universal. Infants

Understands two-word Understands basic word order comprehension combinations (e.g., "mommy kiss Big Bird?") Language (e.g., "wash baby") Understands Understands more complex sentence 170-230 words "Look, Cookie Monster is helping Big Bird.") 15 16 18 28 29 30 3/1 36 Time (months) Plural 1 000 words Language production Produces 200 to 300 words Future tense Past tense 50 words regular 2 word utterances Past tense Adult-like sentence (18-26 months) irregular construction

Language-specific speech perception

Language-specific speech production

"coo" with vowel-like sounds at 3 months of age, and "babble" using consonant-vowel combinations at about 7 months of age. Toward the end of the first year language-specific patterns of speech production begin to emerge in infants' spontaneous utterances. As children approach the age of 2 years, they begin to mimic the sound patterns of their native language. Chinese toddlers' utterances reflect the pitch, rhythm, and phonetic structure of Mandarin, and the utterances of British toddlers sound distinctly British. Infants develop an ability to imitate the sounds they hear others produce as early as 20 weeks of age. Very early in development infants begin to master the subtle motor patterns required to produce their "mother tongue." Speech-motor patterns acquired in the earliest stages of language learning persist throughout life and influence the sounds, tempo, and rhythm of a second language learned later.

The second half of the first year appears to be a sensitive period for speech learning. If infants are exposed to a new language at this time, do they learn? Kuhl exposed American infants to Mandarin Chinese in the laboratory between 9 and 10 months of age and found that the infants learned if exposure occurred through interaction with a human being; infants exposed to the exact same material through television or audiotape with no live human interaction do not learn (Figure 60–3). When tested, the performance of the live-exposure group was statistically indistinguishable from that of infants raised in Taiwan who had listened to Mandarin for 10 months (Figure 60–3). These results established that at 9 months of age the

right kind of exposure to a foreign language permits phonetic learning, supporting the view that this is a sensitive period for phonetic learning. The study also demonstrated, however, that social interaction appears to play an essential role in learning.

What causes the change in infants' perception between 6 and 12 months of age? Studies of infants suggest that early exposure to speech induces an implicit learning process that reduces the infant's initial ability to hear distinctions between foreign-language sounds. At 6 months of age infants begin to organize speech sounds into categories based on phonetic prototypes, ie, the most frequently occurring phonetic units in their language. Six-month-old infants in the United States and Sweden were tested with prototypical English and Swedish vowels to examine whether infants discriminated acoustic variations in the vowels, like those that occur when different talkers produce them. By 6 months of age the American and Swedish infants ignored acoustic variations around nativelanguage prototypes. This "category perception" did not occur with nonnative prototypes. This explains why 11-month-old Japanese infants fail to discriminate English /r/ and /l/ after experience with Japanese. Brain imaging and behavioral tests on infants confirm this change between 7 and 11 months of age.

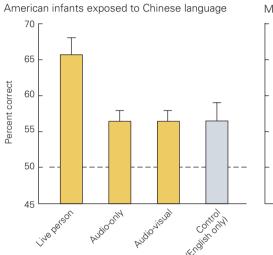

Language Uses the Visual System

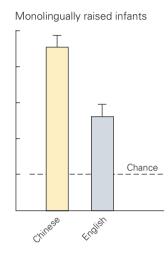

Language is typically communicated through an auditory-vocal channel. However, deaf speakers communicate through a visual-manual channel. Natural

Figure 60-3 Infants can learn the phonemes of a nonnative language at 9 months of age. Three groups of American infants were exposed for the first time to a new language (Mandarin Chinese) in 12 25-minute sessions between the ages of 9 and 10.5 months. One group interacted with live native speakers of Mandarin; a second group was exposed to the identical material through television; and a third group heard tape recordings only. A control group had similar language sessions but heard only English. Performance on discrimination of Mandarin phonemes was tested in all groups after exposure (11 months). Only infants exposed to live Mandarin speakers discriminated the Mandarin phonemes. Infants exposed through TV or tapes showed no learning, and were indistinguishable from the controls (who heard only English). The performance of American infants exposed to live Mandarin speakers was equivalent to monolingual Taiwanese infants of the same age who had experienced Mandarin from birth. (Reproduced, with permission, from Kuhl, Tsao, and Liu 2003.)

signed languages, such as American Sign Language (Ameslan or ASL), are those invented by the deaf and vary across countries. Deaf infants "babble" with their hands at approximately the same time in development as hearing infants babble orally. Other developmental milestones, such as first words and two-word combinations, also occur on the developmental timetable of hearing infants.

Additional studies indicate that visual information of another kind, the face of the talker, is not only very helpful for communication but also affects the everyday perception of speech. We all experience the benefits of "lip-reading" at noisy parties—watching speakers' mouth movements helps us understand speech in a noisy environment. The most compelling laboratory demonstration that vision plays a role in everyday speech perception is the illusion that results when discrepant speech information is sent to the visual and auditory modalities. When subjects hear the sound /ba/ while watching a person pronounce "ga," they report hearing an intermediate articulation /da/. Such demonstrations support the idea that

speech categories are defined both auditorily and visually, and that perception is governed by both sight and sound.

Prosodic Cues Assist Learning of Words and Sentences

Long before infants recognize that things and events in the world have names, they memorize the global sound patterns typical in their language. Infants use the *prosodic* cues in speech—the pitch, duration, and loudness changes—that occur in words to learn these patterns. In English, for example, a strong/weak pattern of stress is typical—as in the words "BAby," "MOMmy," "TAble," and "BASEball"—whereas in other languages a weak/strong pattern predominates. Six and 9-month-old infants given a listening choice between words in English or Dutch show a listening preference for native-language words at the age of 9 months (but not at six months).

Prosodic cues convey both linguistic information (differences in intonation and tone in languages

such as Chinese) and paralinguistic information, such as the emotional state of the speaker. Even in utero infants learn by listening to the prosody of speech produced by their mothers. Certain sounds are transmitted through bone conduction to the womb; these are typically intense (above 80 dB), low-frequency sounds (particularly below 300 Hz, but as high as 1,000 Hz with some attenuation). Thus the prosodic patterns of speech, including voice pitch and the stress and intonation patterns characteristic of a particular language and speaker, are transmitted to the fetus, while the sound patterns that convey phonetic units and words are greatly attenuated. At birth infants demonstrate learning that depends on this prosodic information by showing listening preferences for (a) the language spoken by their mothers during pregnancy, (b) their mother's voice over that of another female, and (c) stories with a distinct tempo and rhythm read by the mother during the last 10 weeks of pregnancy.

Infants Use Transitional Probabilities to Identify Words in Continuous Speech

Seven- to 8-month-old infants recognize words using the probability that one syllable will follow another. The transitional probabilities between syllables in a word are high because the sequential order remains constant. In the word *potato*, for example, the syllable "ta" always follows the syllable "po" (probability of 1.0). Transitional probabilities between words, as between "hot" and "po" in the string "hot potato," are much lower.

Jenny Saffran showed that infants treat phonetic units and syllables with high transitional probabilities as word-like units. In one experiment infants heard 2-minute strings of pseudo-words, such as *tibudo*, *pabiku*, *golatu*, and *daropi*, without any acoustic breaks between them. They were then tested for recognition of these pseudo-words as well as new ones formed by combining the last syllable of one word with the two initial syllables of another word (such as *tudaro* formed from gola*tu* and *daropi*). Infants recognized the original pseudo-words, indicating that they use the transitional probabilities to identify words.

These forms of learning clearly do not involve Skinnerian reinforcement. Caretakers do not manage the contingencies and gradually, through reinforcement strategies, shape the statistical analyses performed by infants. Conversely, language learning by infants also does not appear to reflect a process in which innately provided options are chosen based on language experience. Rather, infants learn language through detailed and sophisticated analysis of the language they hear, an analysis that reveals to them patterns of variation

in natural language. The learning of these patterns in turn alters perception to favor the native language. What infants learn is constrained by the architecture of the brain, and language evolved to capitalize on infant learning. This mirrors the argument that the development of phonetic units was significantly influenced by the features of mammalian hearing, ensuring that infants would find it easy to discriminate phonemes, the fundamental units of meaning in language.

There Is a Critical Period for Language Learning

Children learn language more naturally and efficiently than adults, a paradox given that the cognitive skills of adults are superior. Why should this be the case?

Many consider language acquisition to be an example of a skill that is learned best during a *critical* period in development. Eric Lenneburg proposed that maturational factors at puberty caused a change in the neural mechanisms that control language acquisition. Evidence supporting this view comes from classic studies of Chinese and Korean immigrants to the United States who were immersed in English at ages ranging from 3 to 39 years. When asked to identify errors in sentences containing grammatical mistakes, an easy task for native speakers, second-language learners' performance declined with the age of arrival in the United States. A similar trend emerges when one compares individuals exposed to ASL from birth to those exposed between 5 and 12 years of age. Those exposed from birth were best at identifying errors in ASL, those exposed at age 5 were slightly poorer, and those exposed after the age of 12 years were substantially poorer.

What restricts our ability to learn a new language after puberty? Developmental studies suggest that prior learning plays a role. Learning a native language produces a *neural commitment* to detection of the acoustic patterns of that language, and this commitment interferes with later learning of a second language. Early exposure to language results in neural circuitry that is "tuned" to detect the phonetic units and prosodic patterns of that language. Neural commitment to native language enhances the ability to detect patterns based on those already learned (eg, phonetic learning supports word learning), but reduces the ability to detect patterns that do not conform. Learning the motor patterns required to speak a language also results in neural commitment. The motor patterns learned for one language are often incompatible with those required for pronunciation of the second language and thus can interfere with efforts to pronounce the second language without an accent.

Early in life two or more languages can be easily learned because interference effects are minimal until neural patterns are well established. We know little about how the brain handles the representation of two distinct languages when presented with both initially. The currently favored position is that experience, as well as maturation, are the major factors leading to the developmental critical period for language. Maturation can set the time when the window for learning "opens," but experience can be primarily responsible for determining when the window "closes." Both factors—a maturational development that enables learning and the neural commitment that results from learning—likely operate together to constrain learning a new language later in life.

We do not completely lose the ability later in life to learn a new language. Regardless of the age at which learning begins, second-language learning is improved by a training regime that mimics critical components of early learning—long periods of listening in a social context (immersion), the use of both auditory and visual information, and exposure to simplified and exaggerated speech resembling "motherese."

"Motherese" Enhances Language Learning

Everyone agrees that when adults talk to their children they sound unusual. Discovered by linguists and anthropologists in the early 1960s as they listened to languages spoken around the world, "motherese" (or "parentese," as fathers produce it as well) is a special speaking style used when addressing infants and young children. Motherese has a higher pitch, slower tempo, and exaggerated intonation contours, and is easily recognized.

Compared to adult-directed speech, the pitch of the voice is increased on average by an octave both in males and in females. Phonetic units are spoken more clearly and are acoustically exaggerated, thus increasing the acoustic separation of phonetic units. Adults speaking to infants exaggerate just those features of speech that are critical to their native language. Chinese mothers, for example, exaggerate the four tones in Mandarin that are critical to word meaning in Chinese. Evidence suggests that motherese does in fact assist infants' discrimination of phonetic units.

Infants prefer listening to infant-directed rather than adult-directed speech when given a choice. When infants are allowed to activate recordings of infant-directed or adult-directed speech, by turning left or right, they will turn in whatever direction is required to turn on infant-directed speech.

Several Cortical Regions Are Involved in Language Processing

Language Circuits in the Brain Were First Identified in Studies of Aphasia

Details of the neural basis of language first became apparent in the study of acquired language disorders known as aphasias. Focal brain lesions brought about by cerebrovascular diseases (stroke), head injury, and degenerative diseases such as Alzheimer and Pick disease cause the aphasias. Because language is unique to humans, animal models of language cannot be developed, and the study of aphasia remains an important source of information for elucidating the neural underpinnings of language.

The neural basis of language processing was first outlined in studies of the aphasias in the second half of the 19th century in France by Pierre Paul Broca and in Germany by Karl Wernicke. Based on their work and that of others, Wernicke formulated a model of neural processing of language (see Chapter 1). Most elements of this early model have stood the test of time. Prominent among these is the notion that in most individuals language processing depends more on structures in the left hemisphere than on those of the right. The left cerebral hemisphere is dominant for language in a majority of right-handed individuals and in a smaller but significant majority of lefthanded individuals. Regardless of handedness, in more than 95% of individuals the grammar, lexicon, phonemic assembly, and phonetic production of language depend on the left hemisphere. Languages that rely on visual-motor signs rather than on auditory speech—signed languages such as ASL—also depend on the left hemisphere.

The early study of aphasia also revealed that damage to two brain areas, known as Broca's area in the left lateral frontal region and Wernicke's area in the left posterior superior temporal lobe, was associated with distinct profiles of language disorder, respectively Broca aphasia and Wernicke aphasia.

The Left Hemisphere Is Specialized for Phonetic, Word, and Sentence Processing

Although the conclusion that "we speak with the left hemisphere" is incontrovertible, the origin of that functional separation of the hemispheres during development is unclear. Whether left hemisphere specialization for language derives from a general tendency for the left hemisphere to engage in analytic processing or is a specific linguistic specialization is

not known. Studies by neuroscientist Helen Neville have shown that the left hemisphere is activated not only by auditory stimuli but also by visual stimuli that have linguistic significance. Deaf individuals process visual information in the speech-processing regions of the left hemisphere. Such studies suggest that the speech-related regions of the left hemisphere are well suited to processing expression independent of the modality.

When in development does the left hemisphere become dominant in language processing? Evidence from a variety of sources suggests that left hemisphere specialization for language develops rapidly in infancy. We do not know if left hemisphere dominance for language is present at birth or whether experience with language is required to produce differentiation of the hemispheres; neuroimaging studies on this issue are in progress.

Prosody Engages Both Right and Left Hemispheres Depending on the Information Conveyed

Prosodic information can be linguistic, conveying semantic meaning as tones do in Mandarin Chinese or Thai, and also paralinguistic, expressing our attitudes and emotions. The pitch of the voice carries both kinds of information, and the brain's processing of each kind of information differs. Emotional changes in pitch engage the right hemisphere, primarily in right frontal and temporal regions. A different pattern of brain activity occurs when pitch is used to convey semantic information.

A number of neuroimaging studies have investigated the neural processing of semantic tone. In Thai speakers, for example, the left frontal lobe is consistently activated in response to changes in tone (Figure 60–4). In speakers of a non-tonal language, such as native speakers of American English, or speakers who use tone differently than do Thai speakers, such as Mandarin Chinese speakers, the Thai words do not activate these left hemisphere regions (Figure 60–4).

The fact that the left hemisphere plays the dominant role in phonemic and grammatical processing does not mean that the right hemisphere plays no role in language. Right hemisphere processing of emotional information helps convey a speaker's mood and intentions, and this helps interpret sentence meaning. Patients with right hemisphere lesions often produce speech with inappropriate stress, timing, and intonation, and their speech sounds emotionally flat; they also frequently fail to interpret the emotional cues in others' speech.

The right hemisphere also plays a role in discourse. Patients with damage in the right hemisphere have difficulty ordering sentences into a coherent narrative. They also have difficulty comprehending meaning when the full meaning depends on the relationships among sentences rather than on each sentence taken in isolation. For this reason these patients often fail to understand jokes, and this has an impact in their social lives.

Language Processing in Bilinguals Depends on Age of Acquisition and Language Use

How are multiple languages represented in the human brain? Modern neuroimaging techniques allow bilingual processing to be studied more directly and in greater detail than in earlier studies. They show that both the age at which a second language is acquired and the degree of proficiency in the second language affect how the brain processes multiple languages. In "late" bilinguals (those who learned a second language in adulthood) the second language and native language are processed in spatially separated areas in the language-sensitive left frontal region. In "early" bilinguals (those who acquired both languages as children) the two languages are processed in the same area.

The Model for the Neural Basis of Language Is Changing

On the basis of new observations and the contribution of Norman Geschwind in the 1960s, neurologists further developed Wernicke's model for the neural basis of language. In this revised model, which came to be known as the Wernicke-Geschwind model, Wernicke's area was presumed to analyze the acoustic signals making up words, while Broca's area organized the articulation of speech. The arcuate fasciculus was assumed to be a unidirectional pathway that helped speech production by bringing information from Wernicke's area to Broca's.

In the model both Wernicke's and Broca's areas interact with association areas. Acoustic cues contained in a spoken word are processed by the auditory pathways and reach Wernicke's area, where the meaning of a word is elaborated and then conveyed to higher brain structures, for example in sectors of the inferior parietal cortex. Eventually such patterns are converted into acoustic patterns and transferred by the arcuate fasciculus into Broca's area and turned into vocalizations.

In this model the ability to read and write also depends on Wernicke's and Broca's areas. In the case of reading, Wernicke's area receives signals from areas of visual cortex on the left and activates the corresponding auditory patterns. In the case of writing, auditory activity that represents these patterns is converted into motor outputs in the premotor region (Exner's area) just above Broca's area.

For several years the Wernicke-Gerschwind model provided a useful framework for the investigation of the neural basis of language processes. It also formed the basis for a practical classification of the aphasias that clinical neurologists still use today (Table 60–1). However, details of the model were called into question by the advent of structural magnetic resonance imaging, and the development of psycholinguistics.

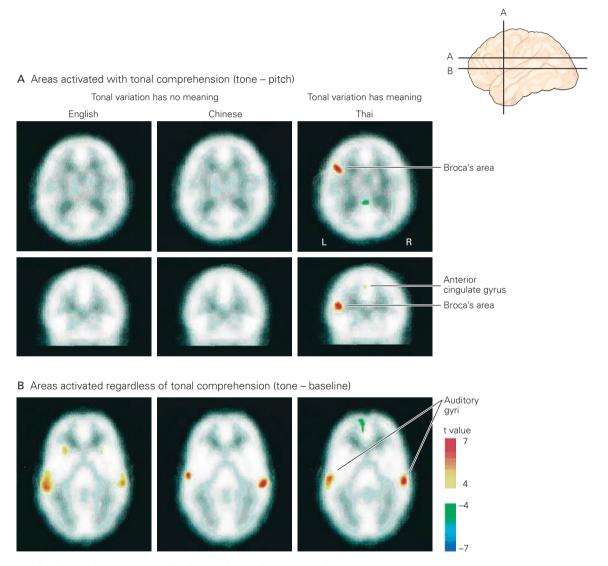

Figure 60–4 Brain activity patterns differ in speakers of tonal and nontonal languages. Positron emission tomography (PET) images show that cerebral blood flow (CBF) differs in Thai, Mandarin Chinese, and American English subjects listening to Thai variations in tone. (Reproduced, with permission, from Gandour et al. 2000.)

A. Only Thai listeners have CBF increases in the left Broca's area and also in the anterior cingulate gyrus. "Tone – pitch" means that the tone task and the pitch task are being compared

using the standard subtraction technique (tone activation minus pitch activation). There is relatively more activation in the tone task compared to the pitch task (the pitch task was used as the reference baseline).

B. The "tone – baseline" condition compares the tone task with a "resting" condition, which is also standard procedure in these studies. All three groups show similar CFB increases in the auditory gyri.

Table 60-1 Differential Diagnosis of the Main Types of Aphasia

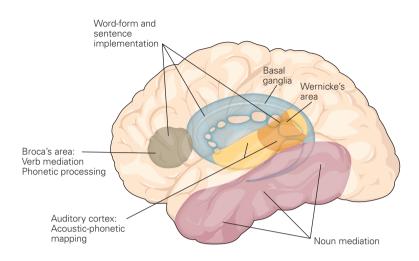

Type of aphasia	Speech	Comprehension	Capacity for repetition	Other signs	Region affected
Broca	Nonfluent, effortful	Largely preserved for single words and gram- matically simple sentences	Impaired	Right hemiparesis (arm > leg); patient aware of defect and can be depressed	Left posterior frontal cortex and underlying structures
Wernicke	Fluent, abundant, well articulated, melodic	Impaired	Impaired	No motor signs; patient can be anxious, agitated, euphoric, or paranoid	Left posterior superior and middle temporal cortex
Conduction	Fluent with some articula- tory defects	Intact or largely preserved	Impaired	Often none; patient can have cortical sensory loss or weakness in right arm	Left superior temporal and supramarginal gyri
Global	Scant, nonfluent	Impaired	Impaired	Right hemiplegia	Massive left perisylvian lesion
Transcortical motor	Nonfluent, explosive	Intact or largely preserved	Intact or largely preserved	Sometimes right- sided weakness	Anterior or superior to Broca's area
Transcortical sensory	Fluent, scant	Impaired	Intact or largely preserved	No motor signs	Posterior or inferior to Wernicke's area

Functional imaging techniques and the direct recording of electrical potentials from the exposed cerebral cortex of patients undergoing surgery for epilepsy opened the possibility for conducting studies in normal individuals engaged in language tasks, and the results of such studies led to revisions of the model.

Together the new approaches have contributed to a better definition of the neural systems responsible for language. The roles of Wernicke's and Broca's areas have expanded, and the arcuate fasciculus is now known to be a bidirectional tract that interconnects larger areas of sensory cortex with prefrontal and premotor areas. Just as importantly, additional areas of the left hemisphere have been found to be involved in language processing. These new areas are located in association areas of the left frontal, temporal, and parietal regions, which appear to provide connections between the processing of concepts and words. Other areas in prefrontal and cingulate areas are thought to exert executive control and mediate working-memory and attentional processes. An additional locus of speech production has been identified in the left insular region. In brief, in the revised version of the model the processing of language requires a far larger network of brain areas than was contemplated earlier.

As suggested by Hanna and Antonio Damasio, the new evidence indicates that three large systems interact to connect language reception and production with conceptual knowledge. Broca's and Wernicke's areas, selected sectors of insular cortex, and the basal ganglia form one system, a language implementation system. This system analyzes incoming auditory signals so as to activate conceptual knowledge and also supports phonemic and grammatical construction and controls speech production. It is anatomically surrounded by a second system, a mediational system, made up of numerous separate regions in the temporal, parietal, and frontal association areas. These regions act as brokers between the implementation system and a third system, a conceptual system, a collection of regions distributed throughout the association areas. In sum, a picture is emerging of a more complex neural network specialized in language processing (Figure 60–5).

Figure 60–5 Language processing involves distributed neural networks. Imaging studies show that language processing involves a more complex and distributed network than previously thought. Particular brain areas are specialized for processing at the phonetic, word, or sentence level.

Brain Injuries Responsible for the Aphasias Provide Important Insights into Language Processing

Broca Aphasia Results from a Large Lesion in the Left Frontal Lobe

Broca aphasia is a disorder of speech production that includes impairments of grammatical processing. Patients have labored and slow speech, articulation is impaired, and the melodic intonation of normal speech is lacking (Table 60-2). Yet patients sometimes have considerable success at verbal communication even when they are difficult to understand because their selection of certain types of words, especially nouns, is often correct. By contrast, verbs as well as grammatical words such as prepositions and conjunctions are poorly selected or can be missing altogether. Another major sign of Broca aphasia is a defect in the ability to repeat complex sentences spoken by the examiner. In general, patients with Broca aphasia give the impression that they comprehend the words and sentences they hear, but suitable tests reveal that comprehension is incomplete.

Because most patients with Broca aphasia give the impression of understanding conversational speech, the condition was initially thought to be a deficit of production only. But Broca aphasics only comprehend sentences whose meaning can be derived from the meaning of the words used. They have difficulty comprehending sentences with meanings that depend mostly on grammar. Broca aphasics can understand *The apple that the girl ate was green* but have trouble understanding *The girl that the boy is chasing is tall*. This

is because the patients can understand the first sentence without recourse to grammatical rules—girls eat apples, but apples do not eat girls; apples can be green, but girls cannot. The patients have difficulty with the second sentence, however, because both girls and boys can be tall, and either can chase the other. To understand the second sentence it is necessary to analyze its grammatical structure, something that Broca aphasics have difficulty doing.

Broca aphasia results from damage to Broca's area (the inferior left frontal gyrus, which contains Brodmann's areas 44 and 45); surrounding frontal fields (the external aspect of Brodmann's area 6, and areas 8, 9, 10, and 46); the underlying white matter, insula, and basal ganglia (Figure 60-6); and a small portion of the anterior superior temporal gyrus. A small sector of the insula, an island of cortex buried deep inside the cerebral hemisphere, can also be included in the correlates of Broca's aphasia. This is because patients who have lesions in a small part of the left insula have difficulty pronouncing phonemes in their proper order. They usually produce combinations of sounds that are very close to the target word, suggesting that they have trouble coordinating the articulatory movements necessary for speech. They have no difficulty perceiving speech sounds or recognizing their own errors and no trouble in finding words.

The structures damaged in Broca aphasia are part of a neural network involved in both the assembly of phonemes into words and the assembly of words into sentences. The network is presumably specialized for relational aspects of language, which include the grammatical structure of sentences and the proper use of grammatical vocabulary and verbs. The other

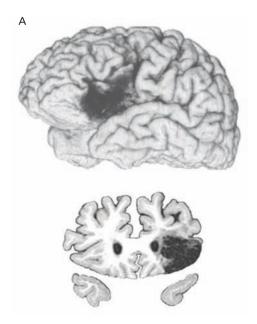

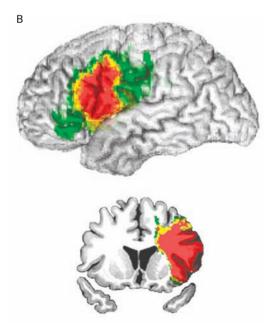

Figure 60–6 Sites of lesions in Broca aphasia. (Reproduced, with permission, from Hanna Damasio.)

A. Top: Three-dimensional MRI reconstruction of a lesion (an infarction) in the left frontal operculum (dark gray) in a patient with Broca aphasia. Bottom: Coronal MRI section of the same brain through the damaged area.

B. Top: Three-dimensional MRI overlap of lesions in 13 patients with Broca aphasia (red indicates that lesions in five or more patients share the same pixels). Bottom: Coronal MRI section of the same composite brain image through the damaged area.

cortical components of the network are located in lateral areas of the left frontal cortex (Brodmann's areas 47, 46, 9), the left parietal cortex (areas 40, 39), and sensorimotor areas above the Sylvian fissure between Broca's and Wernicke's regions (lower sector of areas 3, 1, 2, and 4). The critical subcortical component is in the left basal ganglia (head of the caudate nucleus and putamen). When damage is restricted to Broca's area alone or to its subjacent white matter, the result is the condition of Broca's area aphasia, a milder version of true Broca aphasia from which many patients are able to recover.

Wernicke Aphasia Results from Damage to Left Posterior Temporal Lobe Structures

The speech of patients with Wernicke aphasia is effortless, melodic, and produced at a normal rate, and is thus quite unlike that of patients with true Broca aphasia. The content of the speech, however, is often unintelligible because of frequent errors in the choice of words and phonemes, the order of which determines the word (Table 60–2).

Patients with Wernicke aphasia often shift the order of individual sounds and sound clusters, and add or subtract them to a word in a manner that distorts the intended phonemic plan. These errors are called *phonemic paraphasias* (paraphasia refers to any substitution of an erroneous phoneme or entire word for the intended, correct one). When phoneme shifts occur frequently and in close temporal proximity, words become unintelligible. Even when individual sounds are normally produced, Wernicke aphasics have great difficulty selecting words that accurately represent their intended meaning (known as a verbal or semantic paraphasia). For example, a patient might say *headman* when he means *president*.

Wernicke aphasics have difficulty comprehending the sentences uttered by others. Although this deficit is suggested by the Wernicke-Geschwind model, Wernicke's area is no longer seen as the center of auditory comprehension. The modern view is that Wernicke's area is part of a system that associates speech sounds with concepts. This system includes, in addition to Wernicke's area, the many parts of the brain that subserve grammar, attention, and the knowledge that is the source of the meanings of the words in the sentences

Wernicke aphasia is usually caused by damage to the posterior section of the left auditory association cortex (Brodmann's area 22), although in severe and persisting cases there is involvement of the middle temporal gyrus and deep white matter (Figure 60–7).

Conduction Aphasia Results from Damage to a Specific Sector of Posterior Language Areas

Patients with conduction aphasia comprehend simple sentences and produce intelligible speech. However, like Broca and Wernicke aphasias, they cannot repeat sentences verbatim, they cannot assemble phonemes effectively (and thus produce many phonemic paraphasias) and cannot easily name pictures and objects. Speech production and auditory comprehension are less compromised than in the two other major aphasias (Table 60–2).

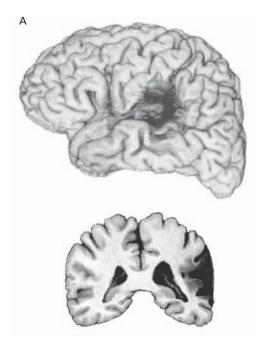

Persistent conduction aphasia is caused by damage to the left superior temporal gyrus and the inferior parietal lobe (Brodmann's areas 39 and 40). The damage can extend to the left primary auditory cortex (Brodmann's areas 41 and 42), the insula, and the underlying white matter.

A recent study by Buchsbaum and colleagues points to a specific subterritory, area Spt located at the boundary of areas 39 and 40, as the region of maximal lesion overlap in cases of conduction aphasia. Area Spt exhibits both auditory and motor responses. In brief, no evidence supports Wernicke's idea that conduction aphasia is caused by a simple interruption or disconnection of the arcuate fasciculus alone. The damage does compromise white matter, as Wernicke predicted, and destroys feed-forward and feedback projections that interconnect areas of temporal, parietal, insular, and frontal cortex. This connectional system seems to be part of the network required to assemble phonemes into words and to coordinate speech articulation.

In spite of the fact that the exact anatomical correlates of conduction aphasia are being revised and that the mechanism of the defect now appears more complex than that proposed in the Wernicke-Geschwind model, it is interesting to note that Wernicke correctly predicted both the main signs of the syndrome and the approximate location of the correlated lesion. The general model still holds.

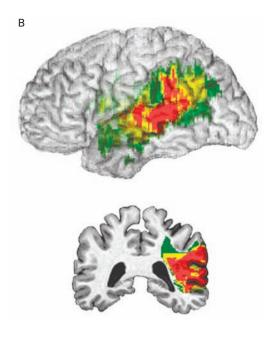

Global Aphasia Results from Widespread Damage to Several Language Centers

Global aphasics are almost completely unable to comprehend language or formulate and repeat sentences, thus combining features of Broca, Wernicke, and conduction aphasias. Speech is reduced to a few words at best. The same word might be used repeatedly, appropriately or not, in a vain attempt to communicate an idea. Nondeliberate ("automatic") speech may be preserved, however. This includes stock expletives (which are used appropriately and with normal phonemic,

phonetic, and inflectional structures), routines such as counting or reciting the days of the week, and the ability to sing previously learned melodies and their lyrics. Auditory comprehension is limited to a small number of words and idiomatic expressions.

Classic global aphasia is accompanied by weakness in the right side of the face and paralysis of the right limbs. It involves damage in three regions: damage to the anterior language region and the basal ganglia and insula, leading to Broca aphasia; damage to the auditory areas of cortex, leading to conduction aphasia; and damage to the posterior language regions, producing Wernicke aphasia. Such widespread damage can only be caused by a stroke in the region supplied by the middle cerebral artery (Appendix C).

Transcortical Aphasias Result from Damage to Areas Near Broca's and Wernicke's Areas

The Wernicke-Geschwind model predicts that aphasias can be caused not only by damage to components of the language system but also to areas and pathways that connect those components to the rest of the brain. Patients with transcortical motor aphasia, such as

Broca aphasics, speak nonfluently, but they can *repeat* sentences, even very long sentences.

Transcortical motor aphasia has been linked to damage to the left dorsolateral frontal area, a patch of association cortex anterior and superior to Broca's area, although there can be substantial damage to Broca's area itself. The left dorsolateral frontal cortex is involved in the allocation of attention and the maintenance of higher executive abilities, including the selection of words. For example, part of the left dorsolateral frontal cortex is activated in functional neuroimaging studies when subjects have to produce the names or actions associated with particular objects (eg, saying "kick" in response to "ball"), and damage to it leaves a patient unable to perform such a task, although they can produce words in ordinary conversation.

The aphasia can also be caused by damage to the left supplementary motor area, located high in the frontal lobe, directly in front of the primary motor cortex and buried mesially between the hemispheres. Electrical stimulation of the area in nonaphasic surgery patients causes the patients to make involuntary vocalizations or to be unable to speak, and functional neuroimaging studies have shown it to be activated

in speech production. Thus the supplementary motor area appears to contribute to the initiation of speech, whereas the dorsolateral frontal regions contribute to ongoing control of speech, particularly when the task is difficult.

Transcortical sensory aphasics have fluent speech, impaired comprehension, and great trouble naming things. The aphasia differs from Wernicke aphasia in the same way that transcortical motor aphasia differs from Broca aphasia: Repetition is spared. In fact, patients with transcortical sensory aphasia might repeat and even make grammatical corrections in phrases and sentences they do not understand. The aphasia thus appears to be a deficit in semantic retrieval, without significant disruption of syntactic and phonological abilities.

Transcortical motor and sensory aphasias are believed to be caused by damage that spares the arcuate fasciculus. This would explain the sparing of repetition skills. Transcortical aphasias are thus the complement of conduction aphasia, behaviorally and anatomically. Transcortical sensory aphasia appears to be caused by damage to parts of the junction of the temporal, parietal, and occipital lobes, which connect the perisylvian language areas with the parts of the brain responsible for word meaning.

Finally, the growing attention given to degenerative brain conditions has permitted a characterization of the primary progressive aphasias (PPA). Their presentation tends to correspond to that of the classical aphasias. The main variants of PPA, as classified by Maria Luisa Gorno-Tempini and colleagues, are *nonfluent/agrammatic*, *semantic*, and *logopenic*.

The Classical Aphasias Have Not Implicated All Brain Areas Important for Language

The cortical sites damaged in the classical aphasias comprise only a portion of language-related areas in the brain. More recent research on aphasia has uncovered several other language-related regions in the cerebral cortex and in subcortical structures. For example, the anterior temporal and inferotemporal cortex have only recently become associated with language.

Damage to the *left* temporal cortex, in Brodmann's areas 21, 20, and 38, causes severe and pure naming defects—impairments of word retrieval without any accompanying grammatical, phonemic, or phonetic difficulty. When the damage is confined to the left temporal pole (Brodmann's area 38), the patient has difficulty recalling the names of unique places and persons but not names for common entities. When the lesions involve the mid temporal sector (areas 21 and 20), the

patient has difficulty recalling both unique and common names. Finally, damage to the left posterior inferotemporal sector causes a deficit in recalling words for particular types of items—tools and utensils—but not words for natural things or unique entities. Recall of words for actions or spatial relationships is not compromised (Figure 60–8).

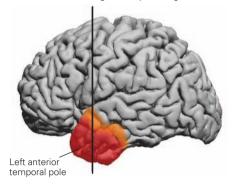

The left temporal cortex contains neural systems that hold the key to retrieving words denoting various categories of things ("tools," "eating utensils"), but not words denoting actions ("walking," "riding a bicycle"). These findings were obtained not only from studies of patients with brain lesions resulting from stroke, head injury, herpes encephalitis, and degenerative processes such as Alzheimer disease, but also from functional imaging studies of typical individuals and from electrical stimulation of these same temporal cortices during surgery.

Areas of frontal cortex in the mesial surface of the left hemisphere, which include the supplementary motor area and the anterior cingulate region (known as Brodmann's area 24), play an important role in the initiation and continuation of speech. Damage in these areas impairs the initiation of movement (akinesia) and causes mutism, a complete absence of speech. In aphasic patients the complete absence of speech is a rarity and is only seen during the very early stages of the condition. Patients with akinesia and mutism fail to communicate by words, gestures, or facial expression because the drive to communicate is impaired, not because the neural machinery of expression is damaged as in aphasia.

Damage to the left subcortical gray nuclei impairs grammatical processing in both speech and comprehension. The basal ganglia are closely interconnected with the frontal and parietal cortex and may have a role in assembling morphemes into words and words into sentences, just as they serve to assemble the components of complex movements into a smooth whole.

Certain brain lesions in adults can cause *alexia*, a disruption of the ability to read, or *agraphia*, a disruption of the ability to write (also known as word blindness). The two disorders may appear combined or separately, and they may or may not be associated with aphasia depending on the site of the causative lesion. Given the very recent emergence of writing (less than 5,000 years ago), and the even more recent emergence of near universal literacy (probably less than a century ago), it is unlikely that a special reading system evolved in the human brain in such a short period of evolutionary time. Therefore pure alexia without aphasia cannot be attributed to impairment of a

A Defective naming of unique images

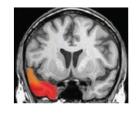

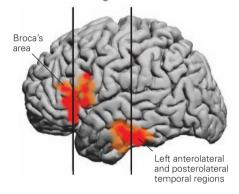

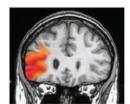

Figure 60–8 Regions of the brain other than Broca's and Wernicke's areas involved in language processing. The study used functional magnetic resonance imaging (fMRI) to study patients with selected brain lesions.

A. The left anterior temporal pole is the region of maximal overlap of lesions associated with impaired naming of unique images, such as the face of a person.

- B. The left anterolateral and posterolateral temporal regions as well as Broca's region are the sites of maximal overlap of lesions associated with impaired naming of nonunique animals.
- C. The left motor cortex and left posterolateral temporal cortex are the sites of maximal overlap of lesions associated with deficits in naming of tools.

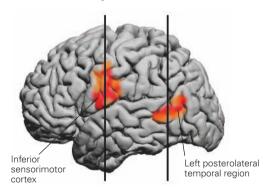

B Defective naming of animals

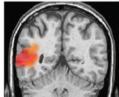

C Defective naming of tools

special reading system in the brain, and is more likely to be caused by a disconnection between the visual and language systems.

Because vision is a bilateral brain process while language is lateralized, pure alexia requires a disruption in the transfer of visual information to the language areas of the left hemisphere. In 1892 the French neurologist Jules Dejerine studied an intelligent and highly articulate man who had recently lost the ability to read, even though he could spell, understand words spelled

to him, copy written words, and recognize them after writing the individual letters. The patient could not see color in his right visual field, but his vision was otherwise intact in both visual fields.

Postmortem examination revealed damage in a region of the left occipital region that disrupted the transfer of visually related signals from *both* the left and right visual cortex to language areas in the left hemisphere. The postmortem also revealed some damage to the splenium, the posterior portion of the corpus

callosum that interconnects left and right visual association cortices. This lesion is no longer believed to be involved in pure alexia, however. When the splenium is cut for surgical reasons without damaging visual cortices, patients can read words normally in the right visual field but not those in the left.

Functional imaging studies have shown that reading words and word-like shapes selectively activates extrastriate areas (secondary visual cortex) anterior to the primary visual cortex in the left hemisphere. This suggests that the processing of word shapes, like other complex visual qualities, requires that general region.

An Overall View

Advances in our understanding of language processing by the brain come from three sources: its acquisition in children, its study in typical individuals using noninvasive brain imaging techniques, and its dissolution in patients suffering brain injury. Studies on infants and children are demonstrating that children, even infants, master the details of language at the phonological, lexical, and syntactic levels very early in development.

Infants begin life capable of responding to subtle acoustic distinctions that cue phonetic differences in the world's languages, distinctions that likely capitalize on general auditory perceptual processes. Very rapidly, a powerful learning process causes infants to recognize statistical properties in the language they hear, allowing them to form phonetic categories, find words in the ongoing stream of discourse, and recognize the phrase structure of their native language, all before 10 months of age. Speech production takes a similar course, showing universal patterns early in life, which show differentiation by about 10 months of age. By the end of the first year, when the infant's first words appear, language learning evolves from universal patterns of speech perception and production to a language-specific pattern. Infant-directed speech ("motherese"), with its enhanced prosodic cues and its exaggerated phonetic units, may assist language learning in the young.

Early language learning being documented in experiments on infants and young children is unrelated to external reinforcement of the kind described by Skinner. Nor does it conform to the process described by Chomsky, by which innately provided options are chosen (or maintained) on the basis of experience. Infant language learning involves a more general sensory and cognitive ability that fine tunes the brain and alters both speech perception and production very early.

The processing of a native language differs from the processing of a foreign language. Taken together, studies show that highly diverse brain regions are involved in language processing and represent a progressive neural commitment to the features and properties of the native language. These findings, and studies of second language acquisition, suggest new models of the critical or sensitive period for language acquisition.

The difficulty in learning a second language later in life appears to be related to experience or expertise, in addition to age of acquisition. Language experience and use commit brain structure to patterns that reflect the primary language so that second language learning is difficult to the degree that it employs a totally different set of phonological and grammatical rules.

Behavioral and brain studies of infants and adults who have been systematically exposed to a foreign language are likely to elucidate the nature of the brain's plasticity for language over a lifetime. Studies of infants who are being raised in bilingual or trilingual homes are likely to answer questions about whether the human brain has limitless potential for language, or whether our ability to acquire multiple languages is constrained. These studies will not only advance our understanding of the neural basis of language but may elucidate general biological principles regarding human learning.

At the same time, studies on the nature of language dissolution in aphasia have made great progress since Broca's and Wernicke's seminal discoveries. They have given us a more complete understanding of linguistic processes and an appreciation of the complex ways in which they interconnect with systems for perception, motor control, conceptual knowledge, and intentions. The challenges to elucidating the neural basis of language remain formidable, although several developments offer the hope of continued progress in the near future.

Improvements in structural imaging will allow more precise and consistent delineation of lesions that affect specific features of language ability. Measurement of brain activity in typical subjects will become increasingly important in the future, as both the spatial and temporal resolution of these techniques improve and the experimental paradigms used to study language become more productive. Neurosurgical candidates whose brain functions must be mapped by stimulation during surgery or by recording from implanted electrode grids that remain in place during everyday activities will be an important source of finegrained information.

Nevertheless, the data available from the past decade of research already suggest two important insights, as noted by Greg Hickok and David Poeppel: The recruitment of brain regions in language studies is highly dependent on the tasks used in the experiment, and language reception may be more bilaterally organized than previously appreciated.

A promising approach is to relate findings on the developmental time course of human language acquisition, plasticity for second language learning, and studies on language dissolution caused by brain trauma. Are the components of language that are learned earliest—those involving prosodic and phonetic learning in speech perception and production—most resistant to change when learning a second language, and also the least likely to suffer from the effects of trauma to the brain? Future research will address these issues.

Understanding the human capacity for language is important for the advancement of fundamental neuroscience and indispensable for the treatment of patients with aphasia, which is one of the most frequent impairments of higher function caused by stroke and head injury (the others are impairments of memory, emotion, and decision making). The astonishing feat of language is too complex to be understood with the tools of any single academic or medical specialty and, as several disciplines come together to study the underlying neural processes, we should expect further significant breakthroughs.

An Overall View

at the end of the 20th century as a major new discipline, a precise meaning of the term *cognition* can often appear elusive. The term is used in different ways in different contexts. At one extreme the "cognitive" in cognitive neuroscience has replaced the older term *information processing*. In this sense cognition is simply what the brain does. When cognitive neuroscientists speak of visual features or motor responses being represented by neural activity, they are using concepts of information processing. From this point of view the language of cognition provides a bridge between descriptions of neural activity and behavior because the same terms can be applied in both domains.

At the other extreme the term "cognition" refers to those higher level processes fundamental to the formation of conscious experience. This is what is meant in the term *cognitive therapy*, an approach to treatment pioneered by Aaron Beck and Albert Ellis and developed from *behavior therapy*. Rather than trying to change a patient's behavior directly, cognitive therapy has the aim of changing the patient's attitudes and beliefs (Box 61–1).

In common parlance the term "cognition" means thinking and reasoning, a usage closer to its Latin root cognoscere (getting to know or perceiving). Thus the Oxford English Dictionary defines it as "the action or faculty of knowing." Indeed, we know the world by applying thinking and reasoning to the raw data of our senses.

Used in this way there can be many kinds of disorders of cognition. After brain damage some patients can no longer understand the raw data supplied by their senses. This type of disorder was first delineated by Sigmund Freud and called an agnosia or loss of knowledge (see Chapter 17). Agnosias can take many different forms. A patient with visual agnosia can see perfectly well but is no longer able to recognize or make sense of what he sees. A patient with prosopagnosia has a specific problem recognizing faces. A patient with auditory agnosia might hear perfectly well but is unable to recognize spoken words.

Cognition is sometimes impaired from birth, so that a person has difficulty in acquiring knowledge. This might lead to general mental retardation or, if the problem is more localized, to specific learning difficulties such as dyslexia (difficulty learning about written language) or autism (difficulty in learning about other minds). Finally, cognition can become aberrant so that the knowledge acquired about the world is false. These disorders of thinking lead to false perceptions

Box 61–1 Cognitive Therapy

Dissatisfaction with psychological treatments based on Freud's theories of unconscious motivation intensified in the middle of the 20th century. Not only did these theories have no relevance to experimental psychology, but more importantly there was no empirical evidence that psychodynamic treatments actually worked.

The first form of alternative psychological therapy to emerge from laboratory studies is known as *behavior therapy*. The fundamental assumption of this approach is that maladaptive behavior is learned and can therefore be eliminated by applying the Pavlovian and Skinnerian principles of stimulus-response learning. So, for example, a child who has been attacked by a dog can become fearful of all dogs. This fearful response can be extinguished if the child learns that the conditioned stimulus (the sight of a dog) is not followed by the unconditioned stimulus (being bitten).

Behavior therapy was shown to be quick and effective for many disorders such as phobias. However, many mental disorders are better characterized in terms of maladaptive thinking rather than maladaptive behavior. In the 1960s Aaron Beck and Albert Ellis initiated a new kind of therapy in which the principles of learning are used to change thoughts rather than behavior. This is known as *cognitive therapy* or *cognitive behavior therapy*.

This form of therapy has been particularly successful in the treatment of depression. Depression is typically associated with negative thoughts (eg, remembering only the bad things that have happened to me) and negative attitudes (believing that I will never achieve my goals). Cognitive therapists teach their clients methods for reducing the frequency of these negative thoughts and changing their negative attitudes into positive ones.

(hallucinations) and false beliefs (delusions) associated with major mental illnesses such as schizophrenia.

Conscious and Unconscious Cognitive Processes Have Distinctive Neural Correlates

Cognition, deriving knowledge through thinking and reasoning, is one of the three components of consciousness. The other two are emotion and will. It used to be taken for granted that thinking and reasoning were under conscious voluntary control, and that cognition was not possible without consciousness. By the end of the 19th century, however, Freud developed a theory of unconscious mental processes and suggested that much human behavior was guided by motivations of which we are not aware.

Of more direct importance for neuroscience was the idea of *unconscious inferences*, originally proposed somewhat earlier by Helmholtz. Helmholtz was the first to carry out quantitative psychophysical experiments and to measure the speed with which signals are conducted in peripheral nerves. It had been thought that sensory signals arrived in the brain immediately (with the speed of light), but Helmholtz showed that nerve conduction was actually quite slow. He also noted that reaction times were even slower. These observations implied that a great deal of brain work

intervened between sensory stimuli and conscious perception of an object. Helmholtz concluded that much of what goes on in the brain is not represented in consciousness and that what does enter consciousness (ie, what is perceived) depends on unconscious inferences. In other words, the brain uses evidence from the senses to decide on the most likely identity of the object that is causing these sensations but does this without our awareness.

This view was extremely unpopular with Helmholtz's contemporaries, and indeed still today. Most people believe that consciousness is necessary for making inferences and that moral responsibility can be assigned only to decisions that are based on conscious inferences. If inferences could be made without consciousness, there could be no ethical basis for praise or blame. Helmholtz's ideas about unconscious inferences were largely ignored.

Nevertheless, by the middle of the 20th century evidence began to accumulate in favor of the idea that most cognitive processing never enters consciousness. After the invention of electronic computers, the discipline of artificial intelligence (AI) was born and researchers began to study how and to what extent machines could perceive the world beyond themselves. It rapidly became clear that many apparently simple perceptual processes, when defined as a set of computations, are actually very complex.

Visual perception is the prime example. In the 1960s almost no one realized how difficult it would be to build machines that could recognize the shape and appearance of objects. We now know that it is very difficult. A fundamental question is how to work out which edges go with which object in a typical cluttered visual scene containing many overlapping objects. No one thought visual perception was difficult because it seemed so easy for us. I look out of the window and I see buildings, trees, flowers, and people. I am not aware of any mental processes behind this perception. Instead, my awareness of all these objects seems instantaneous and direct. The computational approach to vision revealed the underlying neural processes on which our seemingly effortless perception of the world depends. Similar processes underlie all sensory perception and especially the perception of sounds as speech. Most neural scientists now believe that only percepts, but not cognitive processing, are conscious phenomena.

The evidence for unconscious cognitive processes comes not only from artificial intelligence studies but also studies of cognition in people with brain damage. The effects of unconscious processes on behavior can be demonstrated most strikingly in certain neurological patients, such as those with "blind sight," a disorder first delineated in the 1970s by Lawrence Weiskrantz. These patients have lesions in the primary visual cortex and claim to see nothing in the part of the visual field served by the damaged area. However, when asked to guess, they are able to detect simple visual properties such as movement or color far better than is expected by chance. Despite having no sensory-based perception of objects in the blind parts of the visual field, these patients do have unconscious information about the objects and this information is available to guide their behavior.

Another example is unilateral neglect because of lesions in the right parietal lobe (see Chapter 17). Patients with this disorder have normal vision, but they ignore objects on the left side of the space in front of them. Some patients even ignore the left side of individual objects. In one experiment by John Marshal and Peter Halligan patients were shown two drawings of a house. The left side of one house was on fire (Figure 61-1). When asked if there were any differences between the houses, patients replied "no." But when asked which house they would prefer to live in, they chose the house that was not burning. This choice was thus made on the basis of information that was not represented in consciousness. These are just two examples of the abundant empirical evidence for the existence of unconscious cognitive processes in

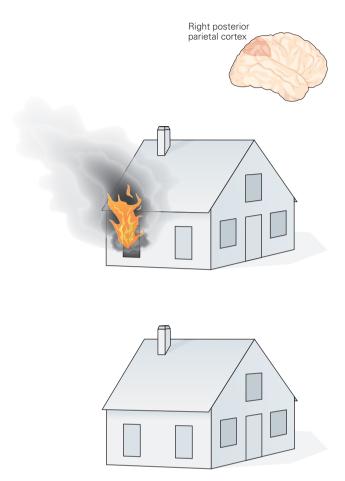

Figure 61–1 Unconscious processing in cases of spatial neglect. After damage to the right parietal lobe many patients seem to be unaware of the left side of space (unilateral neglect syndrome). Shown the two drawings reproduced here, such patients said that the two houses looked the same. However, they also said that they would prefer to live in the lower house, indicating unconscious processing of the fire in the other house. (Adapted, with permission, from Marshall and Halligan 1988.)

addition to the aspects of cognition familiar to us through introspection.

Currently one of the most exciting programs of research in neuroscience concerns the search for the *neural correlates of consciousness* (NCC) initiated by Francis Crick and Christopher Koch (see Chapter 17). The aim of this program is to demonstrate qualitative differences between the neural activity associated with conscious and unconscious cognitive processes. This research is important not only because it may give us answers to the difficult question of the function of consciousness but also because it is relevant to our understanding of many neurological and psychiatric disorders.

The weird experiences and delusional beliefs of patients with certain cognitive disorders were once dismissed as beyond understanding. Cognitive neuroscience provides us with a framework for understanding how these experiences and beliefs can arise from specific alterations in normal cognitive mechanisms.

Differences Between Conscious Processes in Perception Can Be Seen in Exaggerated Form after Brain Damage

In many circumstances perception can change without any change in sensory stimulation. This phenomenon is illustrated by ambiguous figures such as the Rubin figure and the Necker cube (Figure 61–2). In other circumstances a big change in sensory stimulation can occur without the observer being aware of this change—the perception remains constant. A compelling example of this is change blindness.

To demonstrate change blindness two versions of a complex scene are constructed. In one well-known example developed by Ron Rensink the picture consists of a military transport plane standing on an airport runway. In one of the two versions an engine is missing. If these two pictures are shown in alternation on a computer screen, but critically interspersed with a blank screen, it can take minutes to notice the difference even though it is obvious when pointed out. (See Figure 29–3 for another example.)

In light of these examples we can explore some simple questions about the relationship between neural activity and conscious and unconscious cognitive processes. We can identify the neural activity associated with changes in perception when there is no change in sensory stimulation. We can discover whether changes in sensory input are registered in the brain even if not represented in consciousness. We can ask whether there is some qualitative difference between the neural activity associated with conscious as opposed to unconscious processes.

Two important results have emerged from studies that seek to identify the neural activity associated with specific types of percepts. The first is that certain kinds of conscious percepts are related to neural activity in specific areas of the brain. When we perceive the faces in the Rubin figure, there is more activity in the area of the fusiform gyrus, which is specialized for the processing of faces. Those brain areas that are specialized for recognition of certain kinds of objects (faces, words, landscapes, etc.) or for certain visual features (color, motion, etc.) become more active when the object or the feature is consciously perceived (Figure 61–3).

This observation also applies to deviant perception (hallucinations). After degeneration of the peripheral visual system leading to blindness, some patients experience intermittent visual hallucinations (Charles Bonnet syndrome). These hallucinations vary from one patient to another. Some patients see colored patches, others see grid-like patterns, and some even see faces. Dominic ffytche has found that these hallucinations are associated with increased activity in the secondary visual cortex, and the content of the hallucination is related to the specific locus of activity (Figure 61–4).

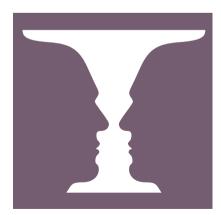

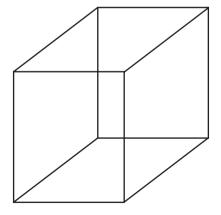

Figure 61–2 Ambiguous figures. If you stare at the figure on the left (the Rubin figure) you sometimes see a vase and sometimes two faces looking at each other. If you stare at the figure on the right (the Necker cube) you see a three-dimensional cube, but the front face of the cube is sometimes seen at the

bottom left and sometimes at the top right. In each figure the brain finds two equally good, but mutually exclusive, interpretations of what is there. Our conscious perception spontaneously alternates between these two interpretations.

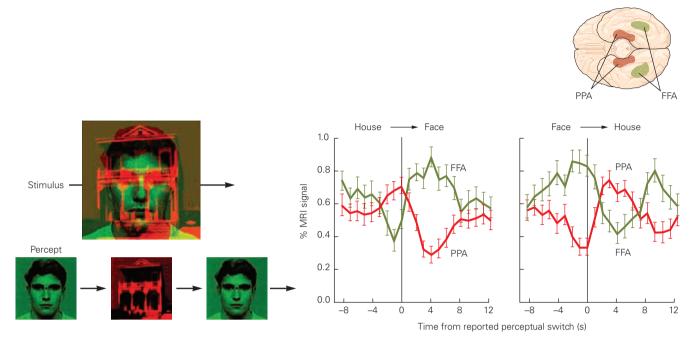

Figure 61–3 Neural activity associated with ambiguous visual information. An ambiguous stimulus was created by simultaneously presenting a face to one eye and a house to the other eye. Brain activity was measured while subjects observed these images. Subjects were instructed to press a button whenever a spontaneous switch in perception occurred

(because of binocular rivalry). When the face is perceived (left), activity increases in the fusiform face area (FFA); when the house is perceived (right), activity increases in the parahippocampal place area (PPA). (Reproduced, with permission, from Tong et al. 1998.)

Schizophrenic patients frequently experience complex hallucinations, which usually have the form of voices talking to or about the patient. These hallucinations are associated with activity in the auditory cortex.

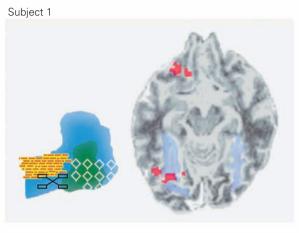

These observations suggest that conscious experience may result from activity in certain cortical regions. This idea is difficult to test experimentally. Nevertheless, in the 1950s the neurosurgeon Wilder Penfield showed that electrical stimulation of the cortex in patients undergoing neurosurgery can give rise to conscious experience. Transcranial magnetic stimulation of the cortex in the region of V5/MT can lead to seeing moving light flashes.

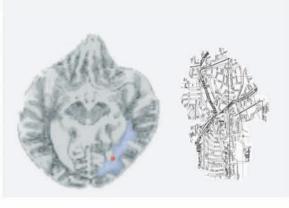

The second important conclusion drawn from studies that seek to correlate neural activity and specific percepts is that activity in a specialized area is necessary but not sufficient to yield conscious experience. For example, in the change blindness paradigm subjects are often unaware of large changes in the picture they are viewing. If the change involves a face, activity is elicited in the fusiform gyrus whether or not the subject is aware of the change. But when the sensory change is also perceived consciously there is, in addition, activity in parietal and frontal cortex (Figure 61–5).

These observations are relevant to our understanding of unilateral neglect. It may be that the damage in the right parietal cortex simply prevents the formation of conscious representations of objects on the left side of space, since objects on the left side still elicit neural activity in the visual cortex. That is, sensory activity may support an unconscious inference in patients that they would not want to live in the house that is burning on the left side.

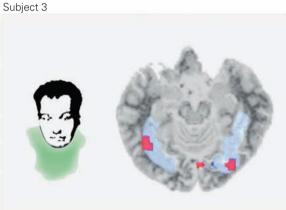

In normal people stimuli that do not enter awareness can nevertheless elicit overt responses. A face with a fearful expression elicits a fear response in the autonomic nervous system, measured as an increase in skin conductance (galvanic response) because of sweating. This response occurs even if the face is immediately followed by another visual stimulus, such that the face is not consciously perceived. There may be an advantage to having a rapid but poor resolution system for avoiding dangerous things. We jump first and only later, on the basis of a slow, high-resolution system, become aware of the identity of the object that made us jump (see Chapter 48). Damage in one or the other of these two recognition systems can explain certain otherwise puzzling neurological and psychiatric disorders.

Subject 2

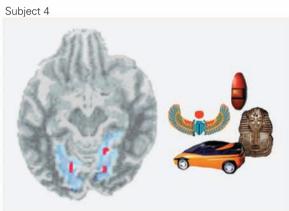

Figure 61-4 Neural activity associated with visual hallucinations. Some patients with damage to the retina experience visual hallucinations. The location of the neural activity and the content of the hallucination are related.

The experience of colors, patterns, objects, or faces, is associated with heightened activity (red) in specific regions of inferior temporal cortex. The fusiform gyrus is shaded blue for reference. (Reproduced, with permission, from ffytche et al. 1998.)

Prosopagnosia is a perceptual disorder in which faces are no longer recognizable. The patient knows he is looking at a face but cannot recognize the face, even the face of his wife. The problem is specific to faces and the visual system. The patient may still be able to recognize his wife from her clothes, her gait, and her voice.

Actually, patients with prosopagnosia are able to identify faces but they do so unconsciously. They show autonomic responses to familiar faces and do better than chance when asked to guess whether or not faces shown to them belong to people who are familiar. In fact, they may use their awareness of the autonomic (emotional) responses elicited by a face to judge familiarity.

Capgras syndrome, a delusion that is occasionally observed in schizophrenic patients and in some neurological patients, shows the opposite pattern. These patients firmly believe that someone close to them, usually a husband or wife, has been replaced by an impostor. They claim that the person, although similar if not identical in appearance, is in fact someone else. Often this delusion is acted on with the demand that the impostor leave the house. In one extreme case a patient accused his stepfather of being a robot and subsequently decapitated him to look for batteries and microfilm in his head.

Haydn Ellis and Andy Young have suggested that this bizarre delusion is the mirror phenomenon of prosopagnosia. According to this view, the processing stream for face recognition is intact, but the stream that mediates the emotional response to the face is not functional. As a result, patients recognize the person in front of them but, because the emotional response is lacking, feel that there is something fundamentally wrong. This account has been partially confirmed by the observation that these patients do not have normal autonomic responses to familiar faces.

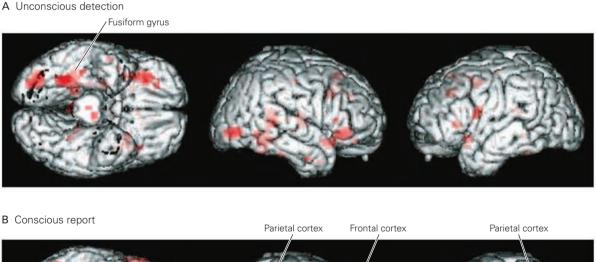

This explanation implies that Capgras delusions are not the consequence of disordered thinking but of disordered experience. A patient sees the face of his wife without having the normal emotional response. The conclusion that this is not his wife but an impostor is a cognitive response to this abnormal experience, the mind's attempt to explain experience.

The Control of Action Is Largely Unconscious

The sense that we are in control of our own actions is a major component of consciousness. But are we aware

of all aspects of our own actions? David Milner and Mel Goodale studied intensively a patient known as D.F. who demonstrates a striking lack of awareness of certain aspects of her own action. As a result of damage to her inferior temporal lobe caused by carbon monoxide poisoning, D.F. suffers from *form agnosia*. She is unable to perceive the shapes of things. She cannot distinguish a square from an oblong card and cannot describe the orientation of a slot. Yet when she picks up the oblong card to place it through the slot she orients her hand and forms her grasp appropriately (Figure 61–6). D.F. is able to use sensory information about the shapes of objects to guide reaching and grasping movements, but this information is not conscious.

This unconscious guidance system is not unique to patients with brain damage. It is simply revealed more starkly in the case of D.F. by the damage to the system that normally brings visual information about shape into consciousness. Indeed, we can all make rapid and accurate grasping movements without being aware of the perceptual and motor information that

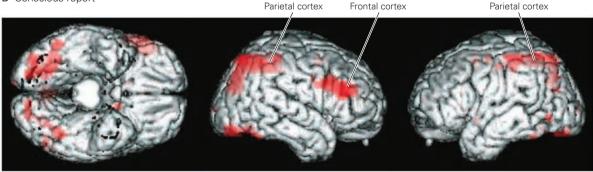

Figure 61–5 Brain activity with and without awareness. Activity in the fusiform face area increased when the face viewed by subjects changed, whether subjects were unaware of the change (A) or conscious of it (B). When subjects were

aware of the change, activity in parietal and frontal cortex also increased. (Reproduced, with permission, from Beck et al. 2001.)

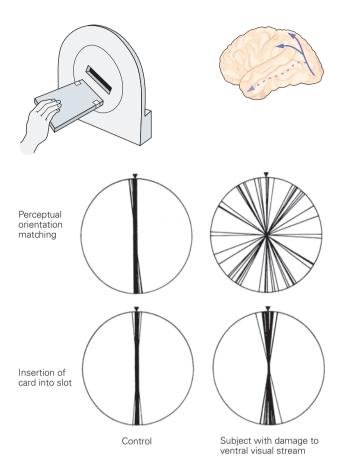

Figure 61–6 Action can be controlled by unconscious stimuli. As a result of damage to the inferior temporal cortex, the patient D.F. is unable to recognize objects based on their shape (form agnosia). She cannot align the tablet with the slot (perceptual matching) because she is not consciously aware of the orientation of either the tablet or the slot. When she is asked to put the tablet through the slot in a quick movement, she orients her hand rapidly and accurately, presumably because the brain mechanisms that drive the movement do not require the subject to identify intellectually the properties of the visual stimuli that guide the movement, but instead use visual mechanisms of which the subject is unaware. (Adapted, with permission, from Milner and Goodale 1995.)

is being used to control these movements. Sometimes we are not even aware of having made the movement. This largely unconscious system for visually guided reaching and grasping is analogous to, and probably overlaps with, the rapid but poor-resolution system associated with fear responses.

Although we may not be aware of the perceptual and motor controls of actions like reaching and grasping, we think we consciously control our actions because we decide on an action and then initiate it.

But what aspects of an action are we actually aware of? In an influential experiment by Benjamin Libet subjects were asked to lift a finger "whenever they felt the urge to do so." During this experiment Libet used EEG to measure the "readiness potential," a change in brain activity that occurs up to one second before a subject makes any voluntary movement. The time at which subjects reported feeling the urge to lift a finger occurred hundreds of milliseconds *after* the beginning of this readiness potential.

Later studies by Patrick Haggard and Martin Eimer revealed that the time of awareness of the urge to act is correlated with the time at which the evoked potential in brain activity measured over the scalp ceases to be medially located and shifts toward the side of the brain that controls the movement, contralateral to the hand that will move. This observation suggests that we are not aware of intending to make a voluntary movement until the nature of that movement has been precisely specified in a motor plan.

The results of these experiments have generated much discussion among philosophers as well as neural scientists concerning the existence of free will. If brain activity can be used to predict when someone is going to act before they are aware of having the urge to perform that act, does this mean that these urges are predetermined and our experience of freely willing them is an illusion? The decision to act might still be made freely but made without awareness. The awareness of the choice comes later. This implies that the unconscious inferences proposed by Helmholtz occur in the motor domain as well as the sensory domain. However, even if we leave open the possibility that free will may operate unconsciously, we are left with the moral dilemma whether people can be held responsible for decisions that are made unconsciously.

Libet also measured the time at which his subjects became aware of *initiating* an action. This awareness is a distinct event, later than the awareness of the urge to act. In contrast to the awareness of the urge, which is later than the associated brain activity, awareness of initiating the act occurs before the act itself begins. The time at which we become aware of initiating a movement occurs some 80 ms before the movement actually starts (Figure 61–7), while any sensory feedback from the movement will occur 100 ms or so after the movement has actually started.

Thus the awareness of initiating a movement is much too early to be based on any sensory feedback. What we are aware of must be based on expected rather than actual sensory information. We are very surprised if the actual sensations do not match what we predicted, as when we pick up an object that is much lighter than

anticipated (see Chapter 33). Furthermore, if the difference between predicted and actual sensations is small, the predicted sensation dominates our awareness.

Pierre Fourneret and Marc Jeannerod required subjects to draw a vertical line using a computer's mouse. The subjects could not see their hand and so could not see that the computer introduced a distortion in the line displayed on the screen. In one test subjects had to move their hand at an angle of 10 degrees to the left to produce a vertical line on the screen (Figure 61-8). In other tests different degrees and directions of distortion were applied. The striking result was that subjects were not aware that the direction of their movements did not match the direction of the line they saw on the screen. When subjects were asked to repeat a movement that had actually deviated 10 degrees to the left, but were not shown the line they were making on the screen, they actually performed the straightforward movement that they thought they had just made. It would seem that as long as the goal is realized (drawing a straightforward line), we are aware of the expected sensory feedback, not the actual sensory feedback.

The idea that we are normally aware of expectations about movements rather than the actual sensations helps us to understand otherwise bizarre experiences. For example, after the amputation of a limb, patients experience a phantom limb (see Chapter 17). Some patients believe they can move this phantom just as they could previously move the real limb. Amputees

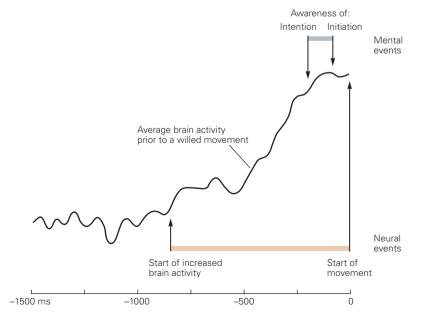

still experience the urge to move the missing limb, and they can select specific movements they want the missing limb to make. As a result, their unconscious sensorimotor systems predict the sensations they would feel if they were to make the movement. It is these predicted sensations that dominate our normal awareness of action and provide the basis for the sensation of a moving phantom limb.

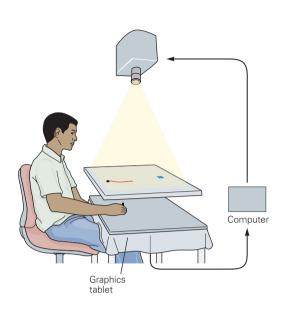

The Conscious Recall of Memory Is a Creative Process

For most of us memory is the conscious reliving of a past experience in our imagination. From a behaviorist point of view, however, memory and learning are processes by which our past experience alters future behavior. Our behavior is often affected by past experience without our being aware of the memory or the influence it is having on us. Once again, such effects are seen in their most striking form in patients with damage to certain areas of the brain.

Some patients become densely amnesic after damage to the medial regions of the temporal lobe (see Chapter 67). These patients show no decline in intellect as measured by IQ tests but cannot remember anything for more than a few minutes. Although devastating, this memory impairment is actually rather circumscribed. The problem is largely manifested in *declarative memory*, and most severely in a type of declarative

Figure 61–7 Mental time is not the same as neural time. When subjects are asked to lift a finger "whenever you feel the urge," a slow change in electrical activity in the brain is detected for up to a second before the finger movement begins (the readiness potential). However, subjects first become aware of the urge to lift their finger several hundred milliseconds after the first detectable change in brain activity. In contrast, their first awareness that the finger is moving is just before the actual movement begins. (Adapted, with permission, from Libet et al. 1983.)

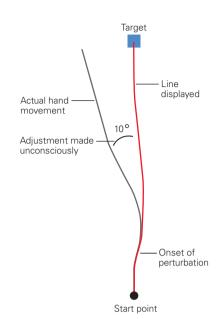

Figure 61–8 Actions can be modified unconsciously. Subjects are asked to draw a straight line with a computer mouse but cannot see their hand, only the line on the screen. The computer is programmed to systematically distort the line displayed on the screen. In the result shown here the subject

had to move his hand 10 degrees to the left to produce a vertical line on the screen. Subjects are not aware of making such adjustments. (Adapted, with permission, from Fourneret and Jeannerod 1998.)

memory called *episodic memory*, the ability to recollect events in one's life (see Chapter 67). *Procedural memory*, in which consciousness has a minor role (see Chapter 66), remains intact. Thus patients still remember motor skills such as riding a bicycle and can often learn new motor skills at a normal rate. These different effects of brain damage on memory can lead to dramatic dissociations. A patient who has been learning some new skill everyday for a week will deny ever having performed the task before. He is then surprised to find how skillful he has become.

Normal people routinely learn skills unconsciously, although this is much more difficult to demonstrate convincingly. Several studies of procedural learning have used "choice reaction-time" paradigms. For example, subjects presented with four buttons that light up in sequence have to press as quickly as possible each button after it lights up. The subject is not told that the buttons light up in a particular sequence. Of course, knowledge of this sequence would enable the subject to predict which signal will come next and thus to respond more rapidly. In fact, responses do become faster once the sequence can be predicted, even when the subject is entirely unable to describe the sequence.

Another widely used protocol tests subjects' ability to recall lists of words they have memorized, a task that taps a form of declarative memory. In the recall

phase a subject is presented with a list of the words that were on the study list plus new words. An amnesic patient has great difficulty with this type of task and may misclassify most of the previously seen words as new since she cannot recall seeing them before. Nevertheless, the brain activity elicited by reading old words is different from that elicited by the new words. Thus there is unconscious recognition of a difference, equivalent to that shown by patients with unilateral neglect or prosopagnosia. Normal subjects usually find this task easy, but they too will occasionally misclassify old words as new; as with amnesiacs, the evoked brain response registers the distinction lost to conscious retrieval (Figure 61–9).

Occasionally a subject misclassifies a new word as an old one. This misclassification amounts to a false memory. Such misclassifications are most likely to occur when the new word is semantically related to one or more of the old words. If the list of old words contained *big, great, huge,* then the new word *large* is likely to be identified as old. One explanation for this is that the perception of the new word *large* has been unconsciously primed by the previous presentation of the old words. Thus the new word *large* is processed easily and quickly. Because the subject is aware of this perceptual fluency, he concludes the word must be familiar and classifies it as old.

This observation emphasizes that memory is a creative process. Our conscious memories are constructed from both conscious recall and unconscious knowledge. To guard against false memories, as with false percepts, we use our knowledge about the world to determine what memories are plausible.

In some patients the process by which memories are screened seems to become dramatically disturbed. If asked what happened yesterday, most patients with amnesia will say that they cannot remember. However, a few will give elaborate accounts that do not correspond to reality. Such false memories are called confabulations. These memories can sometimes be extremely implausible. For example, one patient said that he had met Harold Wilson (a former British Prime Minister) and discussed a building job they were both working on.

In some cases these false memories are arbitrary constructions, as if the patient would rather make

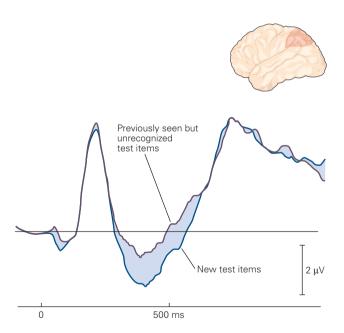

Figure 61–9 Brain activity shows the imprint of forgotten memories. Subjects were presented with several words from a list that included words presented earlier and new words. When asked to identify the words presented earlier, subjects correctly identified some of the old words but forgot others. Immediately after the visual presentation of a word there is a brief fluctuation in the electrical activity (evoked potential) of the brain. Evoked responses in the parietal region of the brain reflect whether or not the words had been seen before, even when subjects did not consciously recognize the words. The pattern produced by old words, whether recognized or not, is different from that produced by the new words. (Reproduced, with permission, from Rugg et al. 1998.)

something up than admit that he does not know. In other cases the false memories are very specific and consistent. For example, one patient with brain damage caused by a fall, studied by Paul Burgess, became convinced that one of the nurses on the rehabilitation ward in England was the same nurse that had looked after him in the intensive care unit in the United States. He also believed that this nurse had stolen his watch and was having an affair with his wife. This patient was able to discuss all other subjects perfectly rationally but was entirely convinced of the truth of his memories about the nurse despite all evidence to the contrary.

False memories of this kind can be indistinguishable from the false beliefs expressed by patients with schizophrenia. Paranoid delusions similar to those described above are common, but some delusions can be even more obviously at odds with reality. One patient studied by Alan Baddeley believed he was a rock guitarist and a Russian chess grand master, even though he cannot play the guitar or chess and does not speak Russian. "But if you don't speak Russian, isn't that rather odd for a Russian chess player?" "Yes, well, I don't speak Russian, but I think it is possible that I've been hypnotized to forget things like the fact that I can speak Russian."

This patient's beliefs seem no longer to be constrained by his knowledge and experience of the world. Furthermore, the problem is self-sustaining as the patient's false beliefs become part of his knowledge of the world. Nevertheless, if our conscious perception and memory were too strongly constrained by our prior knowledge, we would never be able to see anything new or remember anything unusual. The neural mechanisms by which beliefs are acquired and fixed have as yet been only minimally investigated, but the various phenomena described above indicate how a research program might be initiated.

Behavioral Observation Needs to Be Supplemented with Subjective Reports

By the middle of the 20th century it had become clear that the classic behaviorist approach was inadequate for the exploration of many psychological processes. Language acquisition, selective attention, and working memory cannot be understood in terms of relations between stimuli and responses, however complex the relationships postulated.

The demonstration that some cognitive processes are unconscious requires that we move even further from behaviorism. If we want to explore the whole range of conscious and unconscious cognitive processes we will not be able to do so by focusing on overt behavior alone. We must not assume that a subject making purposeful, goal-directed actions is necessarily aware of the stimuli eliciting the action or even of the action itself. We must supplement behavioral observations with subjective reports. We have to ask the subject, "Did you see the stimulus? Did you move your hand?"

During the decades in which psychology was dominated by behaviorism, subjective reports were not considered an appropriate source of data. As a result, methods for recording subjective reports lag far behind methods for studying overt behavior. Regrettably, many studies of cognitive processes still make no systematic attempt to record subjective experience because of the long tradition of excluding subjective reports. One hundred years ago introspection was the major method for obtaining data in psychology. How else could one study consciousness? However, different schools of psychology obtained different results and, as John B. Watson emphasized, there seemed to be no objective way of deciding who was right. How can you independently confirm subjective experience? Thus the method fell into disrepute.

Subjective reports are usually verbal—our subject tells us in words what the experience was like for him or her. But they need not be verbal. In many experiments a human subject may indicate that he or she has seen the stimulus by pressing a button. Pressing a button is an observable behavior, but the behavior is an indicator of a conscious thought.

This kind of nonverbal report can also be used in experiments with monkeys. When presented with an ambiguous figure such as the Rubin vase, a monkey can be trained to press one button when it sees the face and another button when it sees the vase. The choice about which button to press must be based on introspection. Robert Hampton used this technique in a memory experiment. A monkey was asked to distinguish familiar and new objects. This task is typically presented in a forced-choice format. The monkey (or person) is presented with a familiar object and a new object and has to choose the familiar one. A correct choice might occur because the familiar object is consciously recognized. If no conscious recognition occurs then the monkey (or person) must guess. Some of these guesses may be right, because of cues arising from unconscious processes, but many will be wrong.

Incorrect guesses can be avoided if the response "Don't know" is permitted (indicated by not pressing either button). With this format the proportion of button presses that are wrong should be reduced because guesses have been eliminated. Here again the behavior

of pressing the button is partially based on introspection: If I am aware that I do not know the answer, I will not press a button. Monkeys are able to improve their performance (and thus get more food rewards) when given the opportunity not to make a choice, suggesting that they know when they are guessing.

Brain Imaging Can Corroborate Subjective Reports

The problem of verifying subjective reports can be partially addressed with the use of brain imaging. Brain imaging studies have shown that neural activity occurs in localized areas of the brain during mental activity unaccompanied by any overt behavior. The content of such mental activity, such as imagining or daydreaming, can only be known from the subject's reports.

If we scan a subject while he says he is imagining moving his hand, activity will be detected in many parts of the motor system. In most motor regions this activity is less intense than the activity associated with an actual movement, but it is well above resting levels. Similarly, if a subject reports that she is imagining a face she has recently seen, activity can be detected in the "face recognition area" of the fusiform gyrus (Figure 61–10). In these examples the observed neural activity detected by the scanner provides independent confirmation of the experience reported by the subject. The content of consciousness can, in certain limited cases, be inferred from patterns of neural activity.

Malingering and Hysteria Can Lead to Unreliable Subjective Reports

When we record reports of subjective experience we are using the subject like a meter. Just as a meter can convert electrical resistance into the position of a pointer on a dial (reading 100 ohms) so a subject can convert the wavelength of a light source into the report of a color ("I see red.")

But there is a critical way in which the meter is not like a person. The meter does not experience red and cannot communicate meaning. And, while the meter might be faulty, it can never pretend to see red when it is really seeing blue. Most of the time we presume that subjective reports are true, that is, the subject is trying as far as possible to give an accurate description of his experience. But in some circumstances subjects might say "blue" even though what they saw was red. How could this arise and what is the status of the subjective report in such cases?

Consider a patient who has become amnesic as a result of extensive damage to the medial temporal cortex. Shown a photograph of someone whom he sees every day on the ward, the patient denies ever having

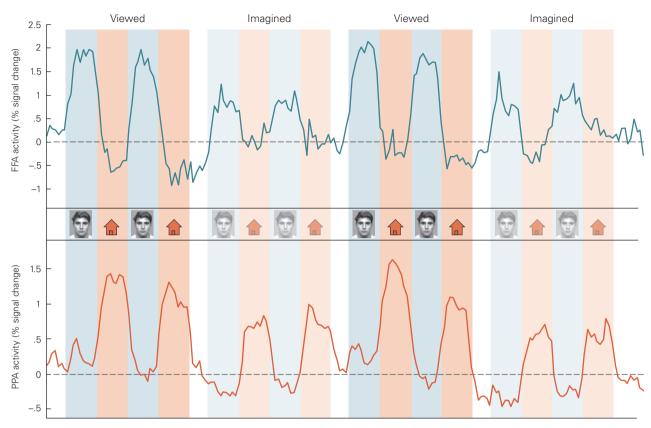

Figure 61–10 Imagining a face or a place correlates with activity in specific areas of the brain. Subjects were scanned while they viewed or imagined faces and houses. In the first block subjects alternately viewed a face or a house. When viewing a face, brain activity increases in the fusiform face area of the inferior temporal lobe (FFA). When viewing a house, brain activity increases in the parahippocampal place area of

the inferior temporal cortex (PPA). In the next block subjects alternately *imagined* a face or a house. The same brain regions are active during both the imagining and direct viewing of faces and houses, although the activity is less pronounced during the imagined viewing. (Reproduced, with permission, from O'Craven and Kanwisher 2000.)

seen this person before. But physiological measurements (electroencephalogram or skin conductance) made at the same time show a response to the photo (but not to photos of people he has not seen before). We conclude that conscious memory processes have been damaged while unconscious processes remain intact. This patient's subjective report is an accurate account of his *conscious* experience, but there are things he "knows" that do not enter consciousness.

Another patient is brought in having been found wandering on the street. There is no evidence of brain damage, but he has lost his memory to the extent of no longer knowing anything about himself or his history. He, too, denies any knowledge of the familiar people he is shown in photographs, but when tested he shows physiological responses to these familiar people. In this case, because of the lack of detectable brain damage (and other features of the memory loss), we begin

to wonder about the truthfulness of his statements. Perhaps the physiological responses indicate that he does consciously recognize people. Subsequently the patient is identified by the police, and we discover that he is wanted for a serious crime committed in the neighboring county. Our doubts about the reliability of his reports increase. Finally, our suspicions are confirmed when he foolishly tells a fellow patient, "It's so easy to fool those clinical psychologists."

In this case we have direct evidence that the patient was deliberately misleading us about his conscious experience. In many ways the ability to deceive is the pinnacle of all human attainments, for to deceive others we must not only be conscious of our own mental state but also of their state. Is there some way we could have discovered from our patient's behavior that he was deceiving us? One approach is to use a memory test of the kind discussed earlier. The patient studies a list of

words. He then sees a new list consisting of the words he has just studied and new words, and he must decide whether each word is old or new. A genuine amnesic would not recognize any of the words. He would have to guess. Through unconscious priming effects he might perform slightly better than chance. The malingering patient can recognize the old words but will have a strong tendency to deny that he has seen them before. Unless he is very sophisticated, he may perform worse than chance. It seems we can distinguish between the genuine amnesic and the malingerer.

A third kind of patient also simulates amnesia (or some other disorder) but does so unconsciously and thus is not a malingerer. Such a case would be called hysterical or psychogenic amnesia. Like the malingerer his performance on the recognition test is worse than chance. Nonetheless, he is not aware of his simulation. The same mechanism probably occurs in normal people who have been hypnotized and then told that they have no memory for what has just happened. This phenomenon is sometimes referred to as a dissociated state; that part of the mind that records experiences and makes verbal reports has become dissociated from the part that is creating the simulation. Hysterical simulations can create sensory loss, such as hysterical blindness, and motor disorders, such as hysterical paralysis or hysterical dystonia, as well as hysterical memory loss.

We are still a long way from understanding the cognitive processes or underlying physiology of these disorders. A key problem is how to distinguish hysteria from malingering. From the standpoint of conscious experience the two disorders are quite different: The malingerer is aware that he is simulating whereas the hysterical patient is not. Yet the patients' subjective reports and overt behavior in the two cases are very similar. Is there no measure that can distinguish between these different disorders? This may be one situation where studies of neural activity are the only way to make the critical distinction between these different states of consciousness.

An Overall View

The study of mental disorders forces us to confront the conceptual gap between the mental and the physical. It is no longer possible to maintain that some mental disorders have mental causes and others physical causes. There is now abundant evidence that a physical cause (abnormal brain function) can create a mental disorder such as the false belief that "My wife has been replaced by an impostor" (Capgras syndrome).

Cognitive neuroscience has had a major impact on our attempts to bridge this gap because its descriptive language, the language of information processing, can be applied simultaneously to psychological and neural processes. In Cartesian terms information is not physical since it is not extended in space or time. Yet information can be stored in physical devices such as memory sticks or books. Information theory and the associated development of the computer provided the first hint that perhaps science can address the question of how subjective experience can emerge from activity in a physical brain.

The cognitive neuroscience approach has been applied to many different mental abnormalities in both neurological and psychiatric patients. These studies have made clear that perception, action, and memory are the result of many parallel processes, and that although some of these processes support conscious experience, the majority occur below the level of awareness.

Striking abnormalities occur when some of these processes are damaged while others remain intact. An example presented in this chapter is D.F., a patient with damage to inferior temporal cortex. She is no longer consciously aware of the shape of an object and hence cannot describe it or recognize what it is. She can nevertheless form her hand into the appropriate shape to pick up the object. From the perspective of cognitive neuroscience, her problem can be described in terms of two kinds of representations that are needed for performing the two kinds of tasks. For reaching and grasping an object, its shape needs to be represented in hand-centered coordinates relating to the position of the hand that will do the grasping. For recognizing an object, an object-centered representation is required that is independent of viewpoint. In D.F. the latter kind of representation has been damaged while the former remains intact.

Although the control of action is largely unconscious, we are very much aware of ourselves as inhabiting and owning our bodies and as agents of action that causes things to happen in the world. These experiences of the self can also be upset by brain abnormalities. Overactivity in the right hemisphere at the junction of the temporal and parietal cortex can create "out-of-the-body" experiences, the experience of looking at one's body from the outside. Damage to the right hemisphere can cause one to look on a limb as "not me." These abnormal experiences can be explained as the result of faulty neural representations of the body and its parts in space.

Even more striking is the disorder of the experience of the self described by patients with schizophrenia.

A patient with "delusions of control" experiences his actions as being under the control of an alien force: "My fingers pick up the pen, but I don't control them. What they do is nothing to do with me." This is not a problem of ownership. The patient knows it is his fingers that are moving. Instead, this is an abnormality in the experience of agency, the awareness of who or what is responsible for the fingers moving. Although we cannot yet describe the cause at the neural level, this symptom is associated with overactivity in parietal cortex, and there is increasing evidence that it is created by a failure to predict the sensory consequences of actions.

Many aspects of motor control occur without consciousness because the feedback sensations associated with movement are actively suppressed. This is because the sensory consequences of our own movements can be predicted on the basis of the information we use to generate the movements. This is why we cannot tickle ourselves. If I stroke the palm of my hand, the conscious sensation and the associated brain activity is greatly reduced in comparison to what occurs if someone else strokes my palm. I can predict what I am going to feel when I tickle myself. I cannot predict what I am going to feel if someone else tickles me. This is a rare example of cognitive neuroscience contributing to our understanding of conscious experience.

We now know why philosophers describe the experience of action as "thin and evasive." For patients with schizophrenia the experience of action is no longer thin and evasive, as the sensory consequences of their actions are not properly suppressed. When they make an active movement with their arm they experience all the sensations that normally occur only when their arm is moved passively by some external force. A cognitive model can thus explain the experience that leads patients with schizophrenia to believe that their actions are caused by alien forces. It remains to be seen whether this cognitive model can also help us understand the abnormality at the neural level.

An Overall View

THE SUCCESS OF NEUROBIOLOGY in providing insights into perception, cognition, and more recently emotion has inspired increasingly sophisticated biological investigations into disorders of thought and mood. In this chapter and the next we examine the four most serious disorders of thinking and mood: schizophrenia, depression, mania, and the anxiety states. These disorders involve disturbances in thought, self-awareness, perception, affect, volition, and social interaction.

In addition to being scientifically challenging, mental illness such as schizophrenia is of great social importance. Tragically this illness results in lifelong disability.

The World Health Organization counts schizophrenia as one of the most significant contributors to disease burden (defined as healthy years of life lost to illness) worldwide. Fully 5% of people with schizophrenia commit suicide. Many more are homeless. The vast majority are unable to function successfully in school or in the workplace. Before the advent of psychopharmacologic therapies, schizophrenia and the mood disorders accounted for more than half of all hospital admissions in the United States. Even now schizophrenia accounts for approximately 30% of all hospitalizations.

The pattern of symptoms of schizophrenia are remarkably similar in all countries and cultures. The average prevalence worldwide ranges between 0.5 and 1%; the male-female ratio is 1.4:1. Diagnosis is usually made during late adolescence or early adulthood with the emergence of full symptoms, but in retrospect the illness begins far earlier with prodromal symptoms.

Diagnosis of Schizophrenia Is Based on Standardized Clinical Criteria

In medicine the understanding of a disease, and therefore its diagnosis, is ultimately based on identification of (1) etiological factors (such as microbes, toxins, or genetic risks) and (2) pathogenesis (mechanisms by which etiologic agents produce disease). Unfortunately, the etiology and pathogenesis of most mental disorders have not been determined. As a result, psychiatric diagnoses still rely on the patient's description of symptoms, the examiner's observations, a detailed natural history (the course of the illness over time), and the response to treatment.

This approach to psychiatric diagnosis began at the turn of the 20th century with the work of Emil Kraepelin in Germany. Influenced by Rudolf Virchow, the German pioneer of cellular pathology, and by Thomas Sydenham, the English clinician who focused attention on the natural history of medical diseases, Kraepelin studied mental disorders as specific disease processes. Even without knowledge about the etiology and pathogenesis, of diseases affecting thought, emotion, and behavior, he argued, such diseases could still be distinguished on the basis of signs, symptoms, and natural history.

Of course, the presentation of a single sign or symptom is not in itself evidence for disease because it may occur in healthy people. But when certain signs and symptoms occur together they form a syndrome, a condition that can be distinguished from normal behavior or from other clusters of signs and symptoms. The natural history of a disease is studied by tracing the onset of signs and symptoms in patients' lives and how they change with time. Thus a syndrome can emerge at a characteristic age or it can follow a characteristic clinical course. For example, Kraepelin recognized that most patients with schizophrenia (which he called dementia praecox) do not recover the level of functioning they had prior to the onset of the disease, whereas most patients with mood disorders experience cycles of relapse and at least partial recovery.

Since the 1980s the diagnosis of psychiatric disorders has been based on standardized criteria that have made diagnosis more reliable. Two different clinicians applying standardized criteria for schizophrenia are very likely to arrive at the same diagnosis. Nevertheless, without etiological or pathophysiological data and lacking objective tests, current diagnostic systems such as the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) of the American Psychiatric Association cannot define disease states in scientifically verifiable terms. With progress in such areas as genetics and neuroimaging, it eventually should be possible to arrive at objectively verifiable and thus valid diagnostic criteria for mental disorders.

The Symptoms of Schizophrenia Can Be Grouped into Positive, Negative, and Cognitive

It is useful to subdivide the symptoms of schizophrenia into three clusters because each may reflect different aspects of the pathophysiology and because each responds differently to the medications presently used. Positive or psychotic symptoms include mental phenomena that do not occur in healthy people, such as hallucinations and delusions. Negative (or "deficit") symptoms result from impairment of normal functions

and can include blunted emotional responses, withdrawal from social interactions, impoverished content of thought and speech (Box 62–1), and a lack of motivation.

A third symptom cluster includes cognitive abnormalities—sometimes described as "disorganization symptoms." These symptoms impair working memory and executive functions—the ability to organize one's life. These cognitive symptoms typically persist even during otherwise successful treatment with medication and are thought to be significant contributors to long-term disability. Interestingly, cognitive symptoms can be found to some degree in persons at very high risk of developing schizophrenia but who have not yet experienced hallucinations or delusions, and in otherwise healthy relatives of patients with schizophrenia, suggesting that cognitive symptoms reflect genetic predispositions to schizophrenia.

The medications used to treat schizophrenia are called antipsychotic drugs and are most effective at diminishing the positive symptoms as well as psychotic symptoms that occur in mood disorders. None of the medications reliably benefits the cognitive symptoms.

Schizophrenia Is Characterized by Psychotic Episodes

The most dramatic manifestations of schizophrenia are psychotic symptoms, including hallucinations and delusions. Hallucinations are percepts that occur in the absence of appropriate sensory stimuli and can occur in any sensory modality. In schizophrenia the most common hallucinations are auditory. Typically, a patient hears voices, but noises or music are also common. Sometimes the voices will carry on a dialog and frequently are experienced as bullying and derogatory. Occasionally, voices will issue commands to the patient that can create a high risk of harm, including suicide. Neuroimaging studies of subjects experiencing auditory hallucinations suggest that areas normally involved in the processing of language are recruited during hallucinations. These include Broca's area in the frontal lobe and Wernicke's area in the superior temporal lobe of the cerebral cortex (see Chapter 60).

Delusions are firm beliefs that are not realistic and not explained by the patient's culture. They can be so powerful that sufferers cannot (or refuse to) compare their beliefs to what is actually happening in the world. Delusions can be quite varied in form. For some patients reality is distorted: The world is full of hidden signs meant only for them (delusions of reference), or they are being closely watched or persecuted (paranoid

Box 62-1 Schizophrenic Speech

Language disturbance is a central feature of schizophrenia and one of the primary behaviors by which it is diagnosed. Grammar is reasonably intact, but content can wander or be incoherent, a symptom that is commonly referred to as "loosening of associations." More bizarre but less common patterns of speech include neologisms (idiosyncratically invented words), blocking (sudden spontaneous interruptions), or clanging (associations based on the sounds rather than the meanings of words, such as "If you can make sense out of nonsense, well, have fun. I'm trying to make cents out of sense. I'm not making cents anymore. I have to make dollars.")

Examples of loosening of associations are:

"I'm supposed to be making a film, but I don't know what is going to be the end of it. Jesus Christ is writing a book about me."

"I don't think they care for me because two million camels \dots 10 million taxis \dots Father Christmas on the rebound."

Question: "How does your head feel?" Answer: "My head, well that's the hardest part of the job. My memory is just as good as the next working man's. I tell you what my trouble is, I can't read. You can't learn anything if you can't read or write properly. You can't pick up a nice book, I don't just mean a sex book, a book about literature or about history or something like that. You can't pick up and read it and find things out for yourself."

Several different types of loosening of associations have been proposed (such as derailment, incoherence, tangentiality, or loss of goal). However, it remains unclear whether these reflect disturbances in fundamentally different mechanisms or different manifestations of a common underlying disturbance, such as the inability to represent a "speech plan" to guide coherent speech. A disturbance of such a mechanism would be consistent with, and may parallel, impairment of control of other cognitive functions in schizophrenia, such as deficits in working memory.

delusions). Others experience bizarre delusions, for example that some entity is inserting or extracting thoughts from their brain or that their dental fillings are radio transmitters broadcasting what they say to nefarious groups. Psychotic symptoms can also occur in mood disorders and drug-induced delirium, but the other symptoms and clinical course of those states are not consistent with schizophrenia.

The full emergence of schizophrenia is often preceded by a period of early symptoms. In this prodromal period the patient can behave eccentrically, become socially isolated, exhibit blunted affect, poverty of speech, a poor attention span, and lack of motivation. Once the disease is fully manifest, periods of florid psychosis typically occur, accompanied by markedly disordered thinking and abnormalities in the regulation of emotion. These periods of overt psychosis are interspersed with periods of residual symptoms. After the first few episodes the patient rarely returns to full normal functioning.

Both Genetic and Nongenetic Risk Factors Contribute to Schizophrenia

Schizophrenia, like many other mental illnesses, runs in families. As early as 1930 Franz Kalman in

Germany studied familial patterns of transmission and concluded that genes contribute significantly to schizophrenia. Three major strategies have been used to quantify the contribution of heredity to the risk of schizophrenia and to understand how genetic risk is transmitted.

In one strategy the rate of concordance for schizophrenia in monozygotic twin pairs, whose DNA sequences are 100% identical, is compared with that in dizygotic twin pairs, whose DNA sequences are on average 50% identical. Assuming that the familial environment is roughly identical for both types of twin pairs, then if genes play a significant role the concordance rates should be higher among monozygotic pairs than among dizygotic pairs. In fact, monozygotic twins have a concordance rate of nearly 50% for schizophrenia, whereas dizygotic twins have a concordance rate of approximately 15% (slightly higher than that for ordinary siblings, which also have on average 50% genetic identity).

Although these rates suggest an important role for genes in schizophrenia, they also demonstrate that genes are not completely determinative. If they were, the concordance rate for monozygotic twins would be 100% as it is in Huntington disease for example. Thus factors other than inherited DNA sequence, such as new mutations, epigenetic modification of DNA,

environmental factors, and stochastic factors occurring during brain development, play a role in converting inherited genetic vulnerability into the disease.

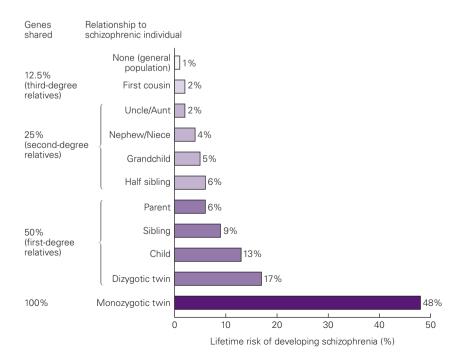

To separate genetic factors and environmental influences more clearly, Seymour Kety, David Rosenthal, and Paul Wender examined children who were adopted at or shortly after birth in Denmark, a country where very accurate family and health records are kept. They found that the rate of schizophrenia in the biological family of an adoptee was much more strongly predictive of schizophrenia than the rate in the adoptive family. Kety and his colleagues also observed that some of the blood relatives of schizophrenic adoptees exhibited some symptoms of schizophrenia, such as social isolation, suspiciousness, eccentric beliefs, and magical thinking, even though they did not have full-blown schizophrenia. These symptoms are part of what is now called schizotypal personality disorder. Kety and his colleagues did not possess modern understandings of working memory, but it would have been interesting to know whether their sample also exhibited the cognitive abnormalities now documented in some relatives of people with schizophrenia. Overall the schizotypal symptoms are thought to be a mild, nonpsychotic form of the disease.

More recently, unaffected monozygotic twins and even siblings of patients with schizophrenia have been found to exhibit some neuroanatomic abnormalities similar to those with the disease. In one magnetic resonance imaging (MRI) study monozygotic twins discordant for schizophrenia had similar deficits in the dorsolateral prefrontal cortex and superior temporal gyrus.

Studies by Irving Gottesman of extended pedigrees of Danish patients with schizophrenia also support the importance of genes. Gottesman noted the correlations between the risk of schizophrenia in relatives and the percentage of the total genetic material each relative shared with the patient. He found a greater lifetime risk of schizophrenia among firstdegree relatives (parents, siblings, and children, who share 50% of the relatives' DNA sequences) than among second-degree relatives (aunts, uncles, nieces, nephews, and grandchildren), who share 25% of their DNA sequences with the patient. Even third-degree relatives (who share only 12.5% of the patient's DNA sequences) were at higher risk for schizophrenia than the 1% of the population at risk for this disease (Figure 62–1).

With the advent of modern genomic technologies during the last decade, progress has been made in identifying variations in DNA sequence that contribute to the risk of schizophrenia. As with many common disorders, risk for schizophrenia has proven to be genetically heterogeneous, with no single gene proving necessary or sufficient. Two forms of genetic variation have been associated with schizophrenia: Variations in single nucleotide bases, and larger chromosomal deletions, duplications, or translocations. In most cases schizophrenia appears to result from the action of a large number of genes together with environmental risk

Figure 62–1 Lifetime risk of schizophrenia as a function of genetic relatedness to a person with schizophrenia. Note that risk increases with increased genetic relatedness but varies within categories of relatedness, reflecting epigenetic effects or new mutations. (Reproduced, with permission, from Gottesman 1991.)

factors. In a minority of cases schizophrenia risk is markedly elevated by chromosomal abnormalities such as a microdeletion on chromosome 22q11.2.

As with any genetically influenced disease, understanding how certain sequences at particular loci in the genome confer risk should provide important clues to pathophysiology, and thus treatment development. Because schizophrenia may result from abnormal developmental processes in the brain, knowing the time during development and adulthood when the genes that predispose to schizophrenia are expressed in the brain would be valuable, as it would suggest different avenues for investigation and might also suggest optimal times for therapeutic intervention.

The complexity of schizophrenia genetics is illustrated by a well-studied chromosomal translocation that was discovered in a large Scottish family. This translocation between chromosomes 1 and 11 inactivates a gene that came to be called Disrupted in Schizophrenia-1 (*Disc-1*) that appears to have significant roles in brain development. Within this multigenerational family, individuals who inherited the translocation exhibit serious mental illness but not necessarily schizophrenia. Some have bipolar disorder and others have major depression. Thus truncations in *Disc-1* must interact with other genes and nongenetic factors to determine the ultimate phenotype.

Attempts to identify objectively measurable components of schizophrenia and other psychiatric disorders have focused on what have been called intermediate phenotypes or endophenotypes. Intermediate phenotypes may represent measurable structural brain abnormalities—cognitive abnormalities (such as deficits in working memory) measured by their neural correlates on functional neuroimaging—or they may represent measurable neurochemical abnormalities. If intermediate phenotypes can successfully be identified, they may simplify the search for risk genes because they may help identify more homogeneous populations for study than those identified by clinical symptoms and interviewing alone.

The search for modifiable environmental risk factors has also proved daunting because some environmental factors that correlate with the disease may be a result rather than a cause of schizophrenia and others may be proxies for the actual, but as yet undiscovered risks. For example, a consistent relationship has been found between schizophrenia and low socioeconomic status. However, the evidence suggests that schizophrenia itself impairs occupational and social success, leading to downward socioeconomic drift, rather than the alternative notion that stressors associated with poverty contribute to the disease. Other environmental risk factors, including season of birth, urban birth,

maternal exposure to viral illness, paternal age, and perinatal complications, have been identified in population studies. Understanding the aspects of urban birth that might contribute to the risk of schizophrenia poses a significant challenge.

Neuroanatomic Abnormalities May Be a Causative Factor in Schizophrenia

Schizophrenia is characterized by certain abnormalities in brain anatomy that can be seen with structural and functional magnetic resonance imaging (fMRI). Thinning of specific areas of the prefrontal, temporal, and parietal cerebral cortex has been observed in many studies (Figure 62–2). The thinning of the prefrontal cortex is most pronounced in the dorsolateral prefrontal cortex, the brain region most critical for working memory.

Thinning in the temporal lobe has been traced to a loss of gray matter in the superior temporal gyrus, the temporal pole, the amygdala (amygdala reductions may be limited to males), and the hippocampus. These regions are normally involved in integrating cognition and emotion. The loss of gray matter is counterbalanced by an increase in the volume of the cerebral ventricles (Figure 62–3).

Structural abnormalities in the brain, such as loss of cortical gray matter, have been correlated with functional abnormalities both in cognitive performance tests and studies with positron emission therapy (PET) or fMRI. Impairment of functions that are dependent on the prefrontal cortex have been particularly well documented. For example, patients with schizophrenia have deficits in working memory and cognitive control, which are correlated in functional neuroimaging studies with lack of activity in the dorsolateral prefrontal cortex.

Loss of Gray Matter in the Cerebral Cortex Appears to Result from Loss of Synaptic Contacts Rather Than Loss of Cells

The observed loss of volume in the frontal and temporal cortical regions is not the result of cell death (loss of cell bodies) but rather a reduction in dendritic, axonal, and synaptic processes (neuropil). As a consequence, the density of cells in the cerebral cortex increases. More cells per unit volume and less total gray matter contribute to enlargement of the ventricular spaces.

Like the prefrontal and temporal cortex, the thalamus also appears smaller in patients with schizophrenia compared to nonaffected individuals. But cell counts in postmortem tissue suggest that, unlike the cerebral cortex, there may be loss of cell bodies in the mediodorsal nucleus of the thalamus. Because cells of

Figure 62-2 Gray matter loss in schizophrenia. Gray matter loss is well documented in schizophrenia; unaffected first-degree relatives also show some loss of cortical gray matter. A study of monozygotic and dizygotic twin pairs discordant for schizophrenia and healthy matched control twins showed that there are significant gray matter deficits in those at genetic risk for schizophrenia. However, among the affected members of twin pairs there are additional, disease-specific deficits in dorsolateral prefrontal, superior temporal, and superior parietal association areas. These reflect the influence of nongenetic factors (eg. developmental or environmental factors). The diseasespecific gray matter loss correlates with symptom severity and degree of cognitive dysfunction rather than with duration of illness or drug treatment. The images here show regional deficits in gray matter in schizophrenic monozygotic twins relative to their healthy co-twins (n = 10 pairs) viewed from the right, left, and right-oblique perspectives. Differences in twins are illustrated by the pseudocolor scale superimposed on cortical surface maps, with pink and red indicating the greatest statistical significance. (Reproduced, with permission, from Cannon et al. 2002.)

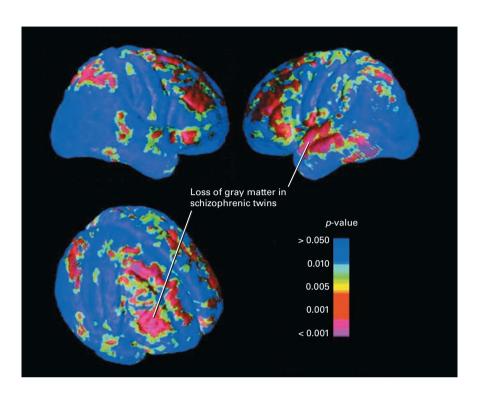

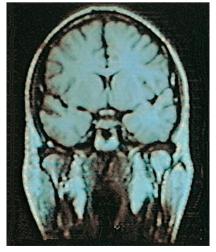

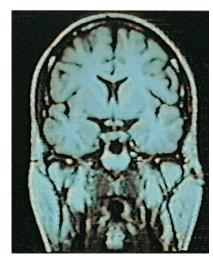

Figure 62–3 Enlargement of lateral ventricles in schizophrenia. This MRI compares monozygotic co-twins discordant for schizophrenia. The affected member of the twin pair has the characteristically enlarged ventricles of schizophrenia. Because there is a wide range of normal ventricular volumes in the population, an unaffected monozygotic twin serves as a particularly appropriate control subject. As with Figure 62–2, this comparison also illustrates the role of nongenetic factors in schizophrenia because monozygotic twins have identical genomes.

Schizophrenic twin

the mediodorsal nucleus send their axons to the dorsolateral prefrontal cortex, loss of these axonal terminals could in turn contribute to the reduction of cortical dendrites and the dendritic spines that usually receive these thalamocortical connections.

Pyramidal neurons, the most common type of excitatory neuron in the neocortex, receive excitatory input from the thalamus on dendritic spines. Thus the reduction in dendrites and dendritic spines (Figure 62–4) would likely signify a loss of synaptic contacts in the dorsolateral prefrontal cortex in schizophrenia. The loss of synaptic connections in this region could possibly explain the impairment of working memory and executive function that characterizes schizophrenia (Figure 62–5).

Abnormalities in Brain Development During Adolescence May Contribute to Schizophrenia

Figure 62–4 Decreased dendritic spine density in schizophrenia. Brightfield photomicrographs illustrate Golgi-impregnated basilar dendrites and spines of pyramidal neurons in layer III in the dorsolateral prefrontal cortex in a normal control subject and two

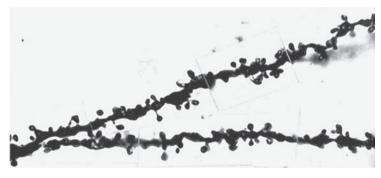

subjects with schizophrenia. Note the loss of dendritic spines in the schizophrenic subjects. (Reproduced, with permission, from Glantz and Lewis 2000.)

Because schizophrenia first occurs typically in late teenage years or in the early twenties, symptoms may be triggered by abnormalities in late stages of brain development. Early adulthood is an important period of brain development, as the brain matures in response to a variety of influences. These range from gonadal steroids in adolescence to stressful life experiences such as separating from parents and siblings for college or military service, or becoming independent by taking on adult responsibilities such as employment and sexual relationships.

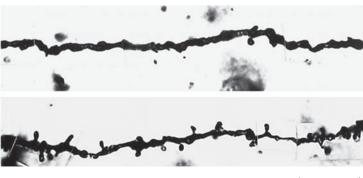

During this period critical life events are accompanied by synaptic pruning that is part of the selective maintenance of those synaptic connections that are used effectively during normal brain development. Synaptic pruning may be particularly important in the prefrontal cortex. Moreover, the pruning coincides with major changes in dopaminergic neurotransmission in this brain area during late adolescence. The timing of these processes is consistent with the implication of both prefrontal cortex and the dopaminergic system in the pathogenesis of schizophrenia (Figure 62–5).

Although slow continued loss of gray matter in prefrontal and temporal cortex has been observed after diagnosis, cortical abnormalities and ventricular enlargement are generally observed at the time of first diagnosis, suggesting that the pathogenic processes underlying schizophrenia have been active long before psychotic symptoms emerge.

Control

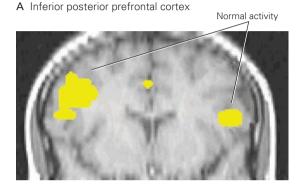

Schizophrenic subjects

10 µm

Brain activity of schizophrenic subjects performing a working memory task

B Dorsolateral prefrontal cortex

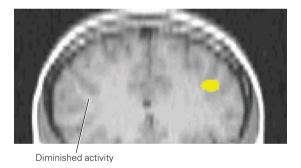

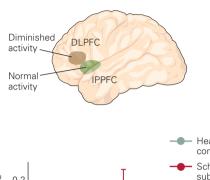

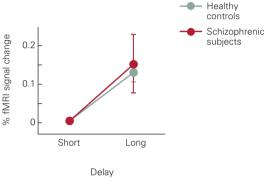

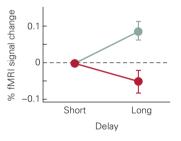

Figure 62–5 Deficits in the function of prefrontal cortex in schizophrenia. Functional MRI (fMRI) was used to examine activity in prefrontal cortex in patients with schizophrenia (first-episode patients who had never been given antipsychotic drugs) as well as healthy controls during performance of a working memory task. Subjects were presented with a sequence of letters and instructed to respond to a particular letter (the "probe" letter) only if it immediately followed another specified letter (the "contextual cue" letter). Demands on working memory were increased by increasing the delay between the cue and the probe letters. A longer delay places greater demands on working memory. The greater demand is hypothesized to require greater activation of prefrontal cortical circuits. (Reproduced, with permission, from Barch et al. 2001.)

A. In both schizophrenic patients and controls activation within Brodmann's area 44/46 increases normally with increases in demand on working memory, suggesting that these inferior posterior regions of prefrontal cortex (IPPFC) have intact function in

schizophrenia. The plot shows the signal change that occurs in the "long-delay" and "short-delay" conditions in healthy controls and patients with schizophrenia based on the activity in the right side of the prefrontal cortex shown in the fMRI scan. Similar effects were observed for activity in the left-side.

B. There is less activity in Brodmann's area 46/49, a region of dorsolateral prefrontal cortex (DLPFC), in patients with schizophrenia relative to healthy controls. Unlike the areas of prefrontal cortex shown in part A, Brodmann's area 46/49 is not activated normally in subjects with schizophrenia. The plot shows that, unlike IPPFC, DLPFC in schizophrenic subjects fails to activate in the long-delay relative to the short-delay condition, consistent with the deficit in working memory function shown by patients with schizophrenia. Selective impairment of one region of prefrontal cortex alongside other regions that appear to have normal function suggests that the impairment is caused by a regionally specific process rather than a diffuse and nonspecific pathophysiological process.

Comparisons of middle-aged and older monozygotic twins that are discordant for schizophrenia (and in which the unaffected twin serves as a control) have shown that the severity of gray matter deficits in the prefrontal cortex correlate with severity of symptoms, not with the duration of illness. Of course, such studies cannot tell us whether the deficits were fully present at the onset of symptoms. To address this issue Judith Rapoport conducted a longitudinal study of those rare individuals with onset of schizophrenia in childhood and documented a correlation between progression of gray matter deficits and ventricular enlargement with

time and duration of illness. In these subjects the normal loss of gray matter during adolescence, presumably related to normal processes of synaptic pruning, was exaggerated (Figure 62–6).

Antipsychotic Drugs Act on Dopaminergic Systems in the Brain

The antipsychotic drugs used to treat schizophrenia all act on the dopaminergic pathways of the forebrain. The first effective antipsychotic drug, chlorpromazine,

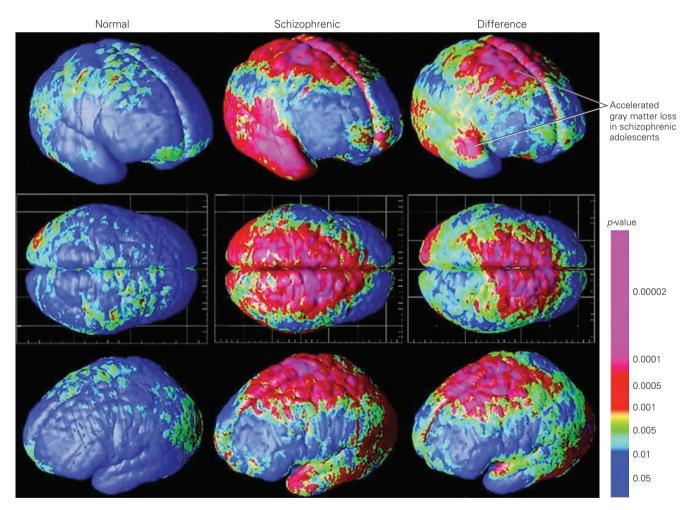

Figure 62–6 Normal loss of gray matter in adolescence is accelerated in adolescents with schizophrenia. The volume of gray matter in parietal, motor, supplementary motor, and superior frontal areas of cerebral cortex is progressively reduced during adolescence because of normal processes of synaptic pruning. In schizophrenic adolescents the loss of gray matter is more pronounced in broad regions of temporal cortex,

including the superior temporal gyrus. The loss of gray matter attributable to schizophrenia (right column) can be determined by comparing the average rates of gray matter loss in normal and schizophrenic adolescents. Significant differences are shown in the pseudocolor scale superimposed on the cortical maps. (Reproduced, with permission, from Thompson et al. 2001)

was developed for its antihistaminic and sedating effects and not for its psychiatric effects. Chlorpromazine was later found to be effective in treating the agitation of patients with schizophrenia and manic depressive illness. Based on these acute calming effects, chlorpromazine and many related drugs were initially described as major tranquilizers. By the mid 1960s, however, it became clear that these drugs were not simply acting as tranquilizers but were specifically reducing the positive symptoms of schizophrenia, such as hallucinations and delusions. They were also effective in treating the psychotic symptoms that can occur in mood disorders, such as mania or severe depression.

The antipsychotic drugs had less impact on the negative symptoms of schizophrenia and little or no impact on cognitive deficits. Patients did improve enough to leave the hospital. Indeed, the widespread use of antipsychotic drugs paved the way for the largescale release of patients with schizophrenia from psychiatric institutions. Unfortunately, these patients did not return to their premorbid level of functioning. The recognition that the sedating properties of early antipsychotic drugs were undesirable side effects led to the development of newer less sedating antipsychotic compounds. In addition, all of the first-generation antipsychotic drugs, with the exception of clozapine, produced Parkinson-like side effects in the extrapyramidal tract such as stiffness, tremor, and difficulty initiating movements.

Because Parkinson disease is caused by the loss of dopaminergic neurons in the midbrain, the occurrence of Parkinson-like symptoms with antipsychotic drug treatment suggested to Arvid Carlsson that these drugs decreased dopaminergic transmission. Following up on this idea, Carlsson established that the antipsychotic drugs block dopamine receptors. Two families of dopamine receptors are known. The D₁ family, which in humans includes D₁ and D₅, are coupled to stimulatory G proteins that activate adenylyl cyclase. The D_2 family, which includes D_2 , D_3 , and D_4 , are coupled to the inhibitory G protein (G_i) that inhibits the cyclase. The D₂ family of receptors has also been shown to signal through an independent pathway involving β arrestin₂ (β -arr₂) and Akt, a protein kinase previously known as protein kinase B. The family of D₁ receptors are expressed in the striatum and are the major type of dopamine receptor in the cerebral cortex and hippocampus, while the D₂ family of receptors is expressed most densely in the striatum, but also in the cerebral cortex, amygdala, and hippocampus. Correlations between receptor binding studies and clinical efficacy in reducing positive psychotic symptoms

indicate that the D_2 family is the main target of the therapeutic actions of antipsychotic drugs on positive symptoms (Figure 62–7).

Antipsychotic drugs not only treat acute relapses of schizophrenia and other psychotic disorders, but continuous treatment with these drugs reduces hospitalization because it markedly increases the time between relapses. Unfortunately, the side effects that occur with administration limit their long-term use. A second generation of antipsychotic medications has been developed based on the observation that clozapine has less likelihood of causing Parkinsonian side effects than the other drugs and can also produce

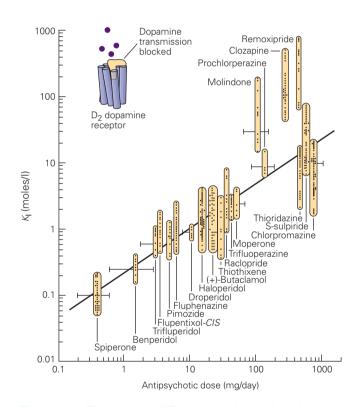

Figure 62–7 The potency of first-generation antipsychotic drugs in treating positive symptoms is strongly correlated with their affinity for D_2 dopamine receptors. On the horizontal axis is the average daily dose required to achieve similar levels of clinical efficacy. On the vertical axis is K_1 , concentration of drug required to bind 50% of D_2 receptors in vitro. The higher the drug concentration required, the lower the affinity of the drug for the receptor. The measurements on the two axes are not entirely independent of each other as the ability of a drug to block dopamine D_2 receptors in vitro is often used to help determine doses to be tested in clinical trials. Clozapine, which does not fall on the line, has significantly greater efficacy than the others, although its mechanism of action is not well understood. (Adapted, with permission, from Seeman et al. 1976.)

therapeutic responses in some patients with schizophrenia for whom other drugs have not worked. (Unfortunately clozapine has other serious side effects that limit its use.)

Based on the properties of clozapine, some of the second-generation drugs were designed to have somewhat lower affinity for D_2 receptors than the first-generation drugs, and some also block the serotonin 5-HT_{2A} receptors, an action that was thought to protect against motor side effects. Recent large-scale clinical trials of the newer drugs have been disappointing, however, showing little incremental benefit over the older antipsychotic drugs. None of the newer drugs is equal to clozapine in efficacy.

Because drugs that reduce positive symptoms do so by blocking D_2 receptors, investigators have asked: What is the role of dopamine in the symptoms of schizophrenia? Although some drugs that block D_2 receptors reduce psychotic symptoms, other drugs that increase dopamine at synapses (such as amphetamine and cocaine) can produce psychotic symptoms, especially paranoid symptoms. Thus Carlsson suggested that dopaminergic systems are hyperactive in schizophrenia.

The most direct evidence for this idea comes from studies in the mid-1990s that found that amphetamine-produced increases in dopamine release were greater in schizophrenic patients than in healthy subjects. These studies suggest that abnormalities in amphetamine-sensitive processes—such as dopamine storage, vesicular transport, dopamine release, or dopamine reuptake by presynaptic neurons—might lead to hyperactivity in the subcortical dopaminergic systems and could contribute to the positive symptoms of schizophrenia, the symptoms that respond to antipsychotic drugs.

Although dopamine activity might increase in subcortical regions of the brain in schizophrenia, there is also some evidence that it might decrease in cortical regions and that this might contribute to the cognitive symptoms. In particular, the number of D_1 dopamine receptors in the prefrontal cortex is thought to be reduced in schizophrenia, an interesting idea because D_1 receptors have been shown to play a role in working memory and executive functions reliant on prefrontal cortex.

Glutamate, the major excitatory neurotransmitter in the brain, also has been implicated in schizophrenia, albeit indirectly. Phencyclidine and ketamine, which block the NMDA-type glutamate receptor and which were originally developed as anesthetic agents, produce psychotic symptoms. In healthy subjects ketamine also produces cognitive dysfunction that mimics, at least to a degree, the cognitive abnormalities seen

in schizophrenia. This has led several investigators to explore the idea that decreased function of NMDA-type glutamate receptors might play a role in producing some of the positive and cognitive symptoms of schizophrenia. These studies indicate that positive and cognitive symptoms are probably the result of abnormalities in several transmitter systems that act either in parallel or in combination with dopamine.

An Overall View

Schizophrenia is a chronic, profoundly disabling disorder characterized by dramatic psychotic symptoms, as well as deficits in emotion, motivation, and cognition. The cognitive deficits impair the ability of people with schizophrenia to regulate their behavior in accordance with reasonable, stable goals. The result is that people with schizophrenia are frequently unable to hold down simple jobs, even at those times when antipsychotic drugs effectively control their hallucinations and delusions.

Once considered a purely psychological reaction to the family environment, it is now clear that schizophrenia is highly influenced by genetic risk factors; indeed, with modern genetic technologies the first convincing risk genes are being identified.

Postmortem studies and neuroimaging are documenting loss of gray matter in the prefrontal and temporal cerebral cortex. Functional neuroimaging is revealing the basis of the disabling cognitive symptoms. Despite this progress, the drugs that we have to treat schizophrenia, as useful as they are, still leave patients seriously symptomatic awaiting new discoveries from neural science.

An Overall View

MOTIONS ARE TRANSIENT RESPONSES to specific stimuli in the environment (eg, the presence of danger), the body (eg, pain), or, for humans, the mind (eg, a train of thought). When an emotional state is prolonged, it can become one's dominant emotional state over time, or mood. Mood thus may be independent of immediate personal and environmental circumstances.

Mood and anxiety disorders are the most common serious disorders of the brain. Mood disorders generally involve either depression or elation. Anxiety disorders involve abnormal regulation of a powerful emotion, fear. In both mood and anxiety disorders the core symptoms have a major emotional component and are accompanied by physiological, cognitive, and behavioral abnormalities.

We discuss disorders of mood and anxiety together because both involve negative emotional states and because they appear to involve overlapping neural circuits that include the amygdala and the anterior cingulate cortex. There also is evidence for overlapping risk factors between major depressive disorder and some anxiety disorders. Commonalities of circuitry and genetic risks, as well as the negative effects of long-term anxiety on a person's mood, may explain the observation that nearly 60% of patients with major depressive disorder also suffer from an anxiety disorder. Anxiety disorder most commonly precedes the onset of depression.

Because emotions are transient responses to stimuli that can be reproduced in the laboratory, they have proven more amenable than moods to neuroscientific study. Objective measurement of moods is difficult, compared with the more stereotypic physiological or behavioral components of emotional responses (see Chapter 48), and experimental approaches to regulating mood have had limited success. Good animal models exist for certain emotions, such as fear and pleasure, and because many features of these states appear to be conserved in evolution, the animal models are relevant to humans (see Chapter 48).

Animal models have allowed detailed investigation of the neural circuitry, physiology, and biochemistry underlying these states. For example, studies of rodent models of instinctive (unlearned) fear and learned fear (in which an animal learns to associate a previously neutral cue with a threat) have elucidated the "fear circuits" centered in the amygdala and the hypothalamus. These circuits activate the sympathetic nervous system to alter heart rate and blood pressure, stimulate secretion of stress hormones, and elicit species-specific defensive behaviors such as motionlessness ("freezing") in rodents and escape behaviors in other species. Such basic investigations are providing testable hypotheses for studies of fear and anxiety and their disorders in humans.

In contrast, neurobiological investigations of moods are less advanced. Although much evidence suggests that animals do have moods, developing empirical methods of ascertaining what those moods are and how they match human experience has been challenging. Most animal models of depression were not developed to investigate the pathophysiology of the human disease, but as empirical screens for anti-depressant drugs. Many of these models are based on chronic stress; although chronic stress and depressed mood have many features in common, they are not identical.

The lack of well-validated animal models of moods and mood disorders has made it difficult to identify the neural circuitry responsible for the regulation and maintenance of moods. Much investigation of mood circuitry has perforce been carried out in humans using noninvasive technologies such as neuro-imaging.

The Most Common Disorders of Mood Are Unipolar Depression and Bipolar Disorder

In the 5th century BC moods were thought to depend on the balance of four humors—blood, phlegm, yellow bile, and black bile. An excess of black bile was believed to cause depression. In fact, the ancient Greek term for depression, *melancholia*, means black bile. Although this explanation of depression seems fanciful today, the underlying view that psychological disorders reflect physical processes is correct.

Only in the past three decades have relatively precise criteria for mood disorders been developed in parallel with those for thought and cognitive disorders (see Chapter 61). Disorders of mood are now classified based on symptoms, natural history (including age of onset, course, and outcome), patterns of familial transmission, and response to treatment. Based on these factors, one can distinguish between two major classes of disorders in people who suffer from depression. Unipolar depression is diagnosed in people who suffer only from depressive episodes; bipolar disorder is diagnosed in individuals in whom depression alternates with episodes of mania (Table 63–1).

Another important distinction is that between primary and secondary mood disorders. Mood disorders caused by drugs (eg, drugs used to treat hypertension) or pathophysiological processes that affect the brain (eg, hypothyroidism) are considered secondary to another condition. The onset of depression late in life also may be secondary to pathophysiological processes such as Parkinson disease or diffuse vascular disease affecting cerebral vessels. Although such cases are important, our discussion here focuses on mood disorders, unipolar and bipolar illnesses, arising as independent pathophysiological processes.

Unipolar Depression Often Begins Early in Life

The key clinical features of unipolar depression can be summarized in Hamlet's words, "How weary, stale, flat, and unprofitable seem to me all the uses of this world!" Untreated, an episode of depression typically lasts 4 to 12 months. The central feature of depression is an unpleasant (dysphoric) mood present most of the day, day in and day out, often accompanied by intense mental anguish, the inability to experience pleasure (anhedonia), and a generalized loss of interest in the world. Sadness is most typical, but anger, irritability, and loss of interest in usual pursuits can predominate in some patients.

Major depression is distinguished from normal sadness or grief by its severity, pervasiveness, duration, and associated symptoms, including physiological, behavioral, and cognitive symptoms (Table 63–1). Physiological symptoms include sleep disturbance, most often insomnia with early morning awakening, but occasionally excessive sleeping; loss of appetite and weight loss, but occasionally excessive eating; and decreased energy. Behaviorally, some depressed patients exhibit slowed motor movements, described

Table 63-1 Symptoms of Mood Disorders

Major Depression

- **A.** Either depressed mood (1) or loss of interest or pleasure (2):
 - 1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (eg, "I feel sad or empty") or observation made by others (eg, "He appears tearful")
 - 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
- B. At least four of the following symptoms are present nearly every day for at least 2 weeks:
 - 1. Significant weight loss when not dieting, or weight gain (eg, a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day
 - 2. Insomnia or hypersomnia nearly every day
 - 3. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
 - 4. Fatigue or loss of energy nearly every day
 - 5. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
 - 6. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
 - 7. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

Manic Episode

- **A.** A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).
- **B.** During the period of mood disturbance three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
 - 1. Inflated self-esteem or grandiosity
 - 2. Decreased need for sleep (eg, feels rested after only 3 hours of sleep)
 - 3. More talkative than usual or pressure to keep talking
 - 4. Flight of ideas or subjective experience that thoughts are racing
 - 5. Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli)
 - 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
 - 7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (eg, engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

Adapted from the Diagnostic and Statistical Manual of Mental Disorders, 4th ed.

as psychomotor retardation, whereas others can be extremely agitated. Cognitive symptoms are evident in both the content of thoughts (hopelessness, thoughts of worthlessness and of guilt, suicidal thoughts and urges) and in cognitive processes (difficulty concentrating, slow thinking, and poor memory).

In the most severe forms of depression psychotic symptoms can occur, including delusions (unshakable false beliefs that cannot be explained by a person's culture) and hallucinations. The psychotic symptoms of depression generally reflect the person's feelings that he or she is worthless or bad. A severely depressed person might, for example, believe that he or she is emitting a potent odor because he or she is rotting from the inside.

The most serious negative outcome from depression is suicide. Suicide is the eighth leading cause of

death in the United States, and the third leading cause of death among young people 15 to 24 years of age. More than 90% of suicides are associated with mental illness, with depression being the leading cause.

In the standard classification of psychiatric disorders in the United States—the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* of the American Psychiatric Association—episodic, primary, unipolar depression that lasts for at least two weeks is classified as major depression. Major depression often begins early in life; approximately one-half of cases occur in those younger than 25 years of age, but first episodes are observed across the life span. Those who have had a first episode in childhood or adolescence have a particularly high likelihood of recurrence. Once a second episode has occurred, a pattern of

repeated relapse and remission generally sets in. Some people do not recover completely from their first acute episode and have chronic, albeit milder, unremitting depression that can be punctuated by acute exacerbations. Chronic, somewhat milder depressions lasting more than 2 years are called *dysthymia*. Although the symptoms of dysthymia are less severe than those of a major depressive episode, the long duration of the symptoms makes this a very disabling illness.

Bipolar Disorder Includes Episodes of Mania

Bipolar disorder is named for its chief symptom, swings of mood between mania and depression. Mania is characterized by euphoria or irritability, a marked increase in energy and a decreased need for sleep, impulsiveness, and excessive engagement in goal-directed behaviors, often with poor judgment characterized by extreme optimism. For example, a person might go on spending sprees well beyond his or her means. During manic episodes self-esteem is inflated, often reaching delusional proportions; individuals might consider themselves to be royalty, prophets, or even deities.

Mania also affects cognition. During a manic episode a person often cannot stick to a topic and might jump quickly from idea to idea, making comprehension difficult. Speech is typically rapid and difficult to interrupt. Psychotic symptoms commonly occur during manic episodes and are generally consistent with the person's elevated mood. For example, people with mania can have delusions that they possess special powers. The symptoms that characterize the depressive episodes in bipolar disorder are indistinguishable from those in unipolar depressions.

Patients who have had at least one manic episode are considered to have bipolar disorder, even if they have not yet experienced a depressive episode. The onset of manic episodes tends to be relatively rapid, occurring over a period of a few days to a few weeks. Bipolar disorder generally begins in young adulthood, uncommonly in childhood. Most episodes lack a clear precipitant, but sleep deprivation can initiate a manic episode, suggesting a relationship between neural systems that regulate circadian rhythms and those that regulate moods. People with bipolar disorder have recurrent episodes of the illness, both manias and depression. However, the rate of cycling between mania, depression, and normal mood (euthymia) varies widely. Between periods of mania or depression some people with bipolar disorder are relatively free of symptoms, but a large fraction have residual symptoms. A few patients have severe, chronic symptoms despite treatment.

Mood Disorders Are Common and Disabling

The lifetime risk of major depressive disorder in the United States is 16.2%. Within any 1 year 6.6% of the population suffers major depression. The prevalence of depression differs in different countries and cultures, but the nature of the symptoms is remarkably similar around the world.

In childhood major depression occurs equally in males and females. After puberty, however, depression occurs more commonly in females independent of culture. In the United States the ratio of females to males with major depression is 1.7:1. Depression is the leading cause of disability worldwide.

In contrast to the high frequency of unipolar depression, bipolar disorder is less common, with a prevalence of 1% that exhibits relatively little variability from country to country. As with major depression, the symptoms are the same across countries and cultures. The risk of bipolar disorder is equivalent in males and females worldwide.

Both Genetic and Nongenetic Risk Factors Play an Important Role in Mood Disorders

As with schizophrenia, both bipolar disorder and major depression run in families with patterns of transmission that are inconsistent with simple Mendelian (single gene) dominant, recessive, or sex chromosomelinked modes of inheritance. One way to estimate the influence of genes on a disease phenotype is to measure the increased risk that results from relatedness to a person who has the disease. This increase in risk can be expressed as a *recurrence risk ratio*. The recurrence risk ratio provides a rough measure of the aggregate influence of genes on a trait but does not provide insight into how many genes might be involved.

Recurrence risk ratios demonstrate that genes contribute to the risk of unipolar depression but exert a much stronger influence on the risk of bipolar disorder (Table 63–2). As in schizophrenia (see Chapter 62), the concordance rates among monozygotic twin pairs (who are genetically identical) are less than 100%. Thus genes alone do not cause mood disorders but must interact with developmental or environmental factors to produce illness.

Overall the genetic risk for mood disorders, like that for schizophrenia, is genetically complex. Genetic linkage and association studies suggest there are multiple pathways of genetic risk for mood disorders, and thus no single gene will likely prove to be either necessary or sufficient.

Table 63–2 Recurrence Risk Ratios (λ) for Mood Disorders and Schizophrenia

Disorder	Siblings	Identical twins
Schizophrenia	9	48
Bipolar disorder	7	60
Major depression	2–3	16

 λ measures the lifetime risk for a disorder as a multiple of the general population risk that results from the degree of relatedness to a person with the disorder. Thus for schizophrenia the base rate in the population is 1%. Given a sibling with schizophrenia there is a ninefold increase in risk (which in this case equals a 9% risk). Given an identical twin with the disorder, the relative risk is 48 times higher than in the general population. Schizophrenia and bipolar disorder are highly genetically influenced, major depression more moderately so.

From the point of view of prevention it is important to sort out the relative roles of genes and environmental risk factors because the latter can be modified. Much evidence suggests that stressful and adverse life events increase the risk of major depression; even here, however, genes may play a role in two ways because they shape a person's temperament. First, temperament plays a role in the kinds of situations into which people place themselves; second, genetic factors can influence the response that people have to adverse life experiences when they do occur. Such interactions between genetic and environmental factors complicate the task of isolating risk factors.

Specific Brain Regions and Circuits Are Involved in Mood Disorders

Because animal models of mood and mood regulation are not fully convincing, investigation of the circuitry involved in mood disorders has relied to a great extent on structural and functional imaging of humans, and to a lesser degree on postmortem analyses of human brains. Neuro-imaging studies of major depression and bipolar disorder have identified abnormalities in brain regions thought to be involved in emotion and cognition (Figure 63–1). Despite progress to date, imaging has not yet identified specific abnormalities in a neural system that can be used reliably to diagnose major depressive or bipolar disorder.

One brain region that has consistently been implicated in both major depressive and bipolar disorders is the gyrus of the anterior cingulate cortex.

This structure runs parallel to the corpus callosum, along the medial surface of each cerebral hemisphere (Figure 63–1). It has two functional subdivisions. A rostral and ventral subdivision is thought to be involved in emotional processes and autonomic function; it has extensive connections to the hippocampus, the amygdala, orbital prefrontal cortex, anterior insula, and nucleus accumbens. A caudal subdivision is thought to be involved in cognitive processes and the control of behavior; it connects with the dorsal regions of prefrontal cortex, secondary motor cortex, and posterior cingulate cortex.

Abnormal function in both subdivisions of the anterior cingulate cortex has been documented in people with mood disorders (Figure 63–2). However, abnormal functioning during major depressive episodes and the depression phase of bipolar disorder has been most consistently found in the rostral subdivision, which is concerned with emotion, and especially in the subgenual region (the region ventral to the genu of the corpus callosum). Indeed, a decrease in activity of the subgenual anterior cingulate gyrus following antidepressant treatment correlates with the success of the treatment (Figure 63–3).

Neuro-imaging also implicates the amygdala and hippocampus in mood disorders. The involvement of the amygdala is not surprising given the wealth of evidence that this structure is involved in the processing of negative emotions, including fear (see Chapter 48). Enlargement of the amygdala has been found in depression, and increases in the basal level of activity in the amygdala have been observed in depression, bipolar disorder, and anxiety disorders. As in many disorders, the volume of the hippocampus may be reduced in depression. This change correlates with the duration of prior episodes of depression and not with the age of the person, consistent with the idea that protracted major depression might produce hippocampal atrophy. Nonetheless, until longitudinal studies are conducted we cannot be certain whether a small hippocampus is a risk factor for depression or a result of it.

Despite the findings that we have described, the use of neuro-imaging to study depression is still in its early stages. Most studies to date have been restricted to anatomical measurement of brain structures or to basal (unstimulated) brain activity in depressed subjects compared with healthy control subjects. Investigators are now beginning to use *activation paradigms*, in which brain activity is measured in response to specific cognitive or emotional stimuli.

Activation paradigms can be a powerful means of identifying brain circuits associated with specific normal and disordered function. For example, in healthy

subjects the anterior cingulate cortex is activated by pain, cognitive conflict, and errors in task performance. Thus the anterior cingulate cortex may ascertain whether behavior is successfully proceeding toward desired goals, and perceived discrepancies between goals and outcomes could contribute to depression.

Depression and Stress Are Interrelated

In some cases depression follows a stressful experience; conversely, the experience of depression is itself stressful. Indeed, depression shares several features with chronic stress, including changes in appetite, sleep, and energy. Major depression and chronic stress may also share biochemical changes, such as persistent activation of the hypothalamic-pituitary-adrenal (HPA) axis (Figure 63–4).

In depressed individuals daily production of the glucocorticoid stress hormone cortisol and secretion of

corticotrophin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) can all be elevated. A transient increase in cortisol secretion, as occurs with acute stress, suppresses the immune system (saving energy and delaying inflammatory processes that might inhibit the fight-or-flight response), shifts the body to a catabolic state (making energy available to confront the cause of the stress), increases energy levels, sharpens cognition, and may increase confidence. However, a chronic increase may contribute to symptoms of depression. For example, people with Cushing disease (in which pituitary tumors secrete excess ACTH leading to excess cortisol) often experience depression and insomnia.

Feedback mechanisms within the HPA axis normally permit cortisol (or exogenously administered glucocorticoids) to inhibit CRH and ACTH secretion and therefore to suppress additional cortisol synthesis and secretion. In approximately one-half of people with major depression this feedback system

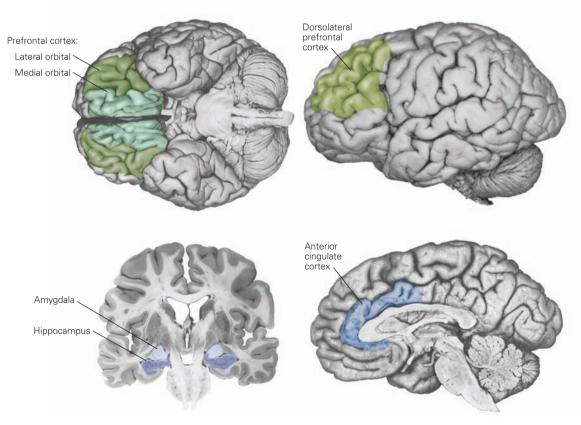

Figure 63–1 Brain centers of emotional dysfunction in patients with depression. Each of these interconnected structures plays a role in regulating emotion and physiological and behavioral responses to emotional stimuli. Abnormalities

in one or more of these regions or in the interconnections among them are associated with failures of emotion regulation. (Reproduced, with permission, from Davidson, Putnam, and Larson 2000.)

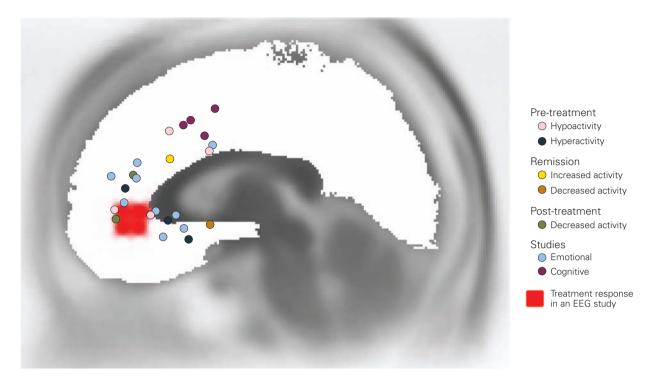

Figure 63–2 Involvement of the anterior cingulate cortex in depression. The figure summarizes the findings of several studies using brain imaging. Colored circles show sites of activation or deactivation before or after treatment of patients with depression. Black circles indicate pretreatment hyperactivity among patients who responded to treatment; green circles indicate posttreatment decreased activity in responders; pink circles indicate hypoactivity in depressed subjects; yellow

circles indicate increased activity with remission of depression; and the sole brown circle indicates decreased activity with remission of depression. Studies involving emotional tasks (blue circles) and cognitive tasks (purple circles) in nonpsychiatric subjects are also shown. The large red area shows the location of treatment response observed in an electroencephalogram (EEG) study of depression. (Adapted, with permission, from Pizzagalli et al. 2001.)

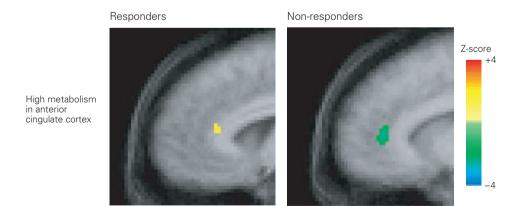

Figure 63–3 Increased activity in the anterior cingulate cortex predicts responsiveness to treatment with antidepressant drugs. Regional cerebral glucose metabolism was measured by positron emission tomography (PET) as a proxy for brain activity. Depressed patients with elevated metabolism

in the rostral anterior cingulate cortex had better responses to antidepressant treatment than those who did not. Cingulate hypermetabolism may represent an adaptive response to depression that predicts antidepressant response. (Reproduced, with permission, from Mayberg et al. 1997).

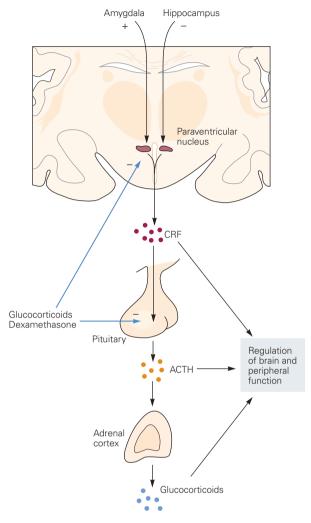

Figure 63–4 The hypothalamic-pituitary-adrenal axis. Neurons in the paraventricular nucleus of the hypothalamus synthesize and release corticotropin-releasing factor (CRF), the key regulatory hormone in this cascade. Secretion of CRF follows a circadian pattern, and the effects of stress are superimposed on this circadian pattern. Excitatory fibers from the amygdala convey information about stress and activate CRF secretion and biosynthesis; inhibitory fibers descend from the hippocampus. CRF enters the hypophyseal portal system and stimulates the corticotrophic cells of the anterior pituitary. These cells synthesize and release adrenocorticotropic hormone (ACTH), which enters the systemic circulation and ultimately stimulates the adrenal cortex to release glucocorticoids. In humans the major glucocorticoid is cortisol; in rodents it is corticosterone. Both cortisol and synthetic glucocorticoids such as dexamethasone act at the level of the pituitary and hypothalamus to inhibit further release of ACTH and CRF respectively. (Adapted, with permission, from Nestler, Hyman, and Malenka 2009.)

is impaired; their HPA axis becomes resistant to suppression even by potent synthetic glucocorticoids such as dexamethasone. Although readily measurable disturbances of the HPA axis are not sensitive or specific enough to be used as a diagnostic test for depression, the observed abnormalities suggest strongly that altered stress responses are an important component of depression in a large proportion of people with the illness.

If recurrent depression causes the decrease in hippocampal volumes described above, it may be that excessive cortisol secretion is the cause. Two theories have been offered to explain how depression might lead to hippocampal atrophy. One is that persistently elevated levels of glucocorticoids can damage mature neurons, perhaps making them more susceptible to glutamate excitotoxicity (see Chapter 43). The other is that elevated cortisol levels or some other aspect of chronic stress suppresses normal neurogenesis (the formation of new neurons), resulting in fewer cells being produced and thus a smaller hippocampus.

In many animals, as well as humans, new granule cells within the dentate gyrus of the hippocampus are produced during adult life. In rodents these new neurons are incorporated into neural circuits. Stressful or aversive experiences as well as glucocorticoids inhibit the proliferation of granule cell precursors and thus suppress normal rates of neurogenesis in the hippocampus. In contrast, antidepressants, including the selective serotonin reuptake inhibitors, increase the rate of neurogenesis. Thus depression might cause hippocampal atrophy by inhibiting neurogenesis and antidepressants might reverse this effect by treating the depression (therefore decreasing stress) and possibly by directly stimulating neurogenesis (by mechanisms that are not yet understood).

These hypothalamic and hippocampal abnormalities may contribute to the symptoms of depression and influence its course. Hypothalamic CRH secretion is under the stimulatory control of pathways from the amygdala and inhibitory pathways from the hippocampus. Damage to the hippocampus could lead to a vicious cycle in which loss of inhibitory control of CRH secretion would lead to greater cortisol release, producing additional hippocampal atrophy. In fact, depression can be accompanied by memory impairments that could be explained by hippocampal dysfunction, either by itself or in conjunction with disturbances in executive function involving the prefrontal cortex, such as failure of attentional mechanisms at the time of memory encoding.

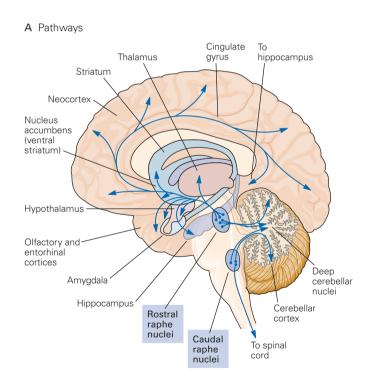

Major Depression Can Be Treated Effectively

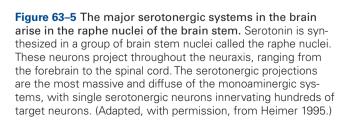

Three types of treatment are effective for major depressive disorder: antidepressant drugs, cognitive-behavioral psychotherapy, and electroconvulsive therapy.

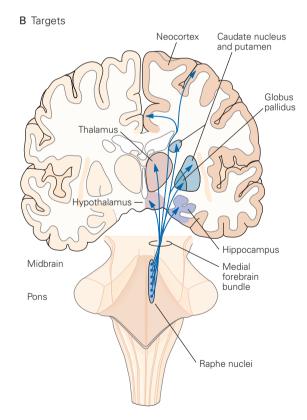

Antidepressant Drugs Target Monoaminergic Neural Systems

The most widely used treatment for depression is antidepressant drugs that act initially on the monoaminergic systems in the nervous system. The monoamines serotonin, norepinephrine, and dopamine—are synthesized in small nuclei within the brain stem (see Figure 46–2). Serotonergic and noradrenergic nuclei are concentrated in the caudal brain stem (Figures 63–5 and 63–6). Most dopamine in the brain is synthesized in more rostral nuclei, the substantia nigra and ventral tegmental area of the midbrain (see Figure 46–2E). Each of the monoaminergic nuclei projects widely throughout the brain; the serotonergic and noradrenergic axons descend into the spinal cord as well. This widespread connectivity permits monoaminergic neurons to produce coordinated responses and thus to influence functions such as arousal, attention, vigilance, motivation, and other cognitive and emotional states that involve multiple brain regions.

Serotonin, norepinephrine, and dopamine are synthesized from amino acid precursors and either packaged into synaptic vesicles for release (see Chapter 12) or else metabolized by the enzyme monoamine oxidase (MAO), which is associated with the outer leaflet of mitochondrial membranes. After release these neurotransmitters bind synaptic receptors or are cleared

A. A sagittal view of the brain illustrates the raphe nuclei. In the brain these nuclei form a fairly continuous collection of cell groups close to the midline of the brain stem and extending along its length. In the drawing here they are shown in more distinct rostral and caudal groups. The rostral raphe nuclei project to a large number of forebrain structures.

B. This coronal view of the brain illustrates some of the major structures innervated by serotonergic neurons of the raphe nuclei.

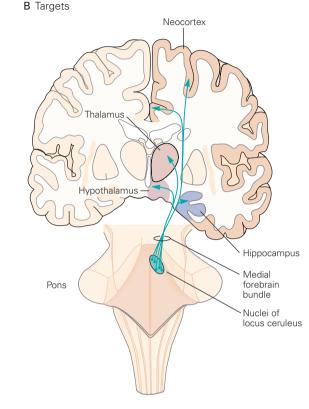

Figure 63–6 The major noradrenergic projection of the forebrain arises in the locus ceruleus. (Adapted, with permission, from Heimer 1995.)

A. Norepinephrine is synthesized in several brain stem nuclei, the largest of which is the nucleus locus ceruleus, a pigmented nucleus located just beneath the floor of the fourth ventricle in the rostrolateral pons. A lateral midsagittal view demonstrates the course of the major noradrenergic pathways from the

locus ceruleus and lateral brain stem tegmentum. Axons from the locus ceruleus project rostrally into the forebrain and also into the cerebellum and spinal cord; axons from noradrenergic nuclei in the lateral brain stem tegmentum project to the spinal cord, hypothalamus, amygdala, and ventral forebrain.

B. A coronal section shows the major targets of neurons from the locus ceruleus.

from the synapse by specific transporters located on the presynaptic cell membrane.

Serotonin and norepinephrine each have a variety of receptors on the presynaptic terminals as well as postsynaptic target cells. There are at least 14 distinct serotonin receptors in humans, divided into seven major classes denoted 5-HT₁ through 5-HT₇ (Table 63–3). Norepinephrine receptors can be divided into two major classes, the α and β adrenergic receptors, with multiple subtypes (Table 63–4). With the exception of the 5-HT₃ receptor, serotonin, norepinephrine, and dopamine act on G protein-coupled receptors that initiate signaling cascades that produce long-term changes in the response properties of the postsynaptic neuron. It is thought that antidepressant drugs are able to alter the responsiveness of the brain to diverse cognitive and emotional stimuli by directly

or indirectly influencing G protein-coupled receptors expressed in large numbers of neurons.

The most widely used antidepressant drugs fall into several major groupings, each of which affects the monoaminergic systems in different ways (Figure 63–7). The *monoamine oxidase inhibitors*, such as phenelzine and tranylcypromine, were the first effective antidepressants. They are highly effective against both depression and anxiety disorders but are rarely used today because of their side effects. MAO inhibitors may exert their effects on depression by blocking the capacity of MAO to break down norepinephrine, serotonin, or dopamine in presynaptic terminals, thus making extra neurotransmitter available for packaging into vesicles and for release.

Two forms of MAO, types A and B, are found in the brain. Type A is also found in the gut and liver,

Table 63-3 Serotonin Receptors

Receptor	G-Protein linkage	Locations in the brain
5-HT _{1A}	$G_{i/o}$	Cerebral cortex, hippocampus, septum, amygdala, dorsal raphe

5-HT ₇	$G_{\rm s}$	Cerebral cortex, hypothalamus, thalamus

where it catabolizes bioactive amines that are present in foods. Inhibition of MAO-A permits bioactive amines such as tyramine to enter the bloodstream from foods that contain it in high concentrations, such as aged cheeses. These amines are taken up by sympathetic neurons through transporters, thus displacing

endogenous monoamines. This process may result in massive release of norepinephrine and epinephrine, resulting in severe elevations of blood pressure. The MAO inhibitors that have been most widely used as antidepressants inhibit MAO-A and MAO-B nonselectively or MAO-A alone, and thus require that patients

Table 63-4 Norepinephrine Receptors

Receptor	G-Protein linkage	Locations in the brain

avoid foods with a high monoamine content. A selective MAO-B inhibitor, selegiline, which has been used to treat Parkinson disease, has recently proved effective in treating depression. But at antidepressant doses, which are higher than for Parkinson disease treatment, it loses its selectivity.

The *tricyclic antidepressants*, such as imipramine, amitriptyline, and desipramine, inhibit either norepinephrine or serotonin transporters or both. These drugs are effective against depression and many anxiety disorders. But they also block many other neurotransmitter receptors, including the muscarinic acetylcholine, histamine H-1, and α_1 noradrenergic receptors, producing side effects such as dry mouth, drowsiness, urinary retention, and postural hypotension, thus limiting their use. Some newer drugs, such as venlafaxine and duloxetine, block both norepinephrine and serotonin but lack the tricyclic structure and the unwanted receptor interactions of the older drugs.

The *selective serotonin reuptake inhibitors*, such as fluoxetine, sertraline, and paroxetine, are widely used. As their name implies, they inhibit the uptake of serotonin selectively. They are effective for major depressive disorder, many anxiety disorders, and, in high doses, for obsessive-compulsive disorder.

In addition to their role in the pharmacologic treatment of mood disorders, the monoamine neurotransmitters may also play a role in pathogenesis. However, much of the evidence for such a link has come from the actions of antidepressant drugs themselves. Because effective treatments may exert their beneficial effects indirectly, the role of monoamines in pathogenesis remains quite uncertain.

Interest in the monoamines began in the 1950s when it was observed that reserpine, an alkaloid derived from the rauwolfia plant, then used to treat hypertension, precipitated depression in approximately 15% of people who received the drug. Reserpine depletes the brain of norepinephrine, serotonin, and dopamine by blocking the ability of presynaptic neurons to take up these neurotransmitters into synaptic vesicles. As a result, the neurotransmitters remain in the cytoplasm where they are degraded by monoamine oxidase. In a serendipitous discovery, iproniazid, a drug that was initially developed to treat tuberculosis, was found to have antidepressant properties. Because of its side effects, iproniazid itself is no longer in use, but it proved to be the prototype MAO inhibitor.

Because depression could be induced by reserpine, which depletes monoamines, and could be ameliorated by MAO inhibitors, which protects monoamines from degradation, the idea emerged that depression

involved a decrease in the availability of monoamines. Further support for this idea came from the discovery of tricyclic antidepressants, which block the uptake of synaptically released norepinephrine and serotonin, thereby prolonging the action of these neurotransmitters within the synapse. These observations led to the hypothesis that depression results from a deficiency of monoaminergic synaptic transmission and that clinically effective antidepressants work by increasing the availability of monoamines at synapses.

A major weakness with this simple hypothesis comes from the observation that the inhibitory actions of antidepressants on monoamine uptake or on MAO are rapid and occur even with the first dose of medication, whereas several weeks of treatment are required to observe a lifting of the depression clinically. Attempts to explain this delay have led to several ideas. Enhancement of serotonergic or noradrenergic synaptic transmission stimulates a large number of preand postsynaptic receptors and activates downstream signaling pathways, some of which activate gene expression and ultimately protein synthesis. One general hypothesis is that, over weeks, newly synthesized proteins alter the responsiveness of neurons or cause the remodeling of synaptic connections in a manner that treats the depression. However, this hypothesis is not supported by any evidence of the genes and proteins that might be responsible or the cells and circuits in which they might exert their effects. One recently discovered mechanism by which antidepressants can regulate gene expression is by causing covalent modification of histone proteins and thus the conformation of chromatin. This type of mechanism might also contribute to the ability of antidepressant responses to persist even after treatment has been completed.

An additional hypothesis is based on the observation, described above, that antidepressant drugs enhance the rate of neurogenesis in the dentate gyrus of the hippocampus. According to this hypothesis the therapeutic delay in antidepressant response would result from the slow time course of development of new neurons and their incorporation into circuits. Some experiments suggest that inhibition of neurogenesis blocks the action of antidepressants in some rodent models of stress, but other experiments suggest that even if hippocampal neurogenesis plays a role in antidepressant action, it is not absolutely necessary.

The slow onset of existing antidepressant drugs is not only a scientific puzzle but also a serious clinical problem. While waiting for their symptoms to improve patients may become demoralized and a minority may be at increased risk of suicidal thoughts and acts. The search for rapidly acting antidepressants

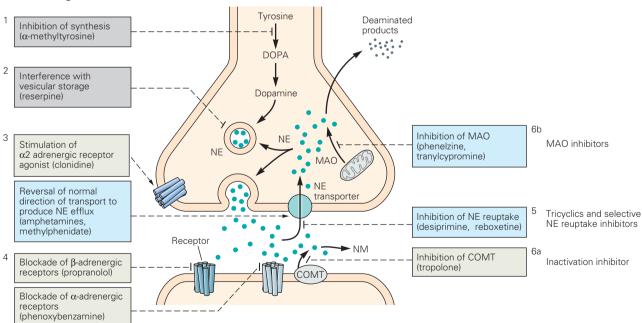

Figure 63–7 (Opposite) Actions of antidepressant drugs at serotonergic and noradrenergic synapses. The figure shows the pre- and postsynaptic sides of serotonergic and noradrenergic synapses. Serotonin and norepinephrine are synthesized from amino acid precursors by enzymatic cascades. The neurotransmitters are packaged in synaptic vesicles; free neurotransmitter within the cytoplasm is metabolized by monoamine oxidase, an enzyme that is associated with the abundant mitochondria found in presynaptic terminals. On release, serotonin and norepinephrine interact with several types of pre- and postsynaptic receptors (see Tables 63–3 and 63–4). Each neurotransmitter is cleared from the synapse by a specific transporter. The serotonin and norepinephrine transporters and monoamine oxidase are targets of antidepressant drugs.

A. Important sites of drug action at serotonergic synapses. Not all actions described are shown in the figure.

- 1. Enzymatic Synthesis. p-Chlorophenylalanine can inhibit the rate-limiting enzyme tryptophan hydroxylase, which initiates the cascade that converts tryptophan to 5-OH-tryptophan, the precursor of 5-hydroxytryptophan (5-HT, serotonin).
- 2. Storage. Reserpine and tetrabenazine interfere with the transport of serotonin and catecholamines into synaptic vesicles by blocking the vesicular monoamine transporter, VMAT₂. The cytoplasmic serotonin is degraded (see A. 6. below) and thus the neuron is depleted of neurotransmitter. Reserpine was used as an antihypertensive drug, but commonly caused depression as a side effect.
- **3.** Presynaptic Receptors. Agonists at presynaptic receptors produce negative feedback on neurotransmitter synthesis or release. The agonist 8-hydroxy-diprolamino-tetraline (8-OH-DPAT) acts on 5-HT_{1A} receptors. The antimigraine triptan drugs (eg, sumatriptan) are agonists at 5-HT_{1D} receptors.
- **4.** Postsynaptic Receptors. The hallucinogen lysergic acid diethylamide (LSD) is a partial agonist at 5-HT_{2A} receptors on the postsynaptic serotonergic neurons. Second-generation antipsychotic drugs, such as risperidone and olanzapine, are antagonists at 5-HT_{2A} receptors in addition to their ability to block D_2 dopamine receptors. The antiemetic compound ondansetron is an antagonist at 5-HT_3 receptors, the only ligand-gated channel among the monoamine receptors. Its key site of action is in the medulla.
- 5. Uptake. The selective serotonin reuptake inhibitors, such as fluoxetine and sertraline, are selective blockers of the serotonin transporter. The tricyclic drugs have mixed actions; some, such as clomipramine, are relatively selective for the serotonin transporter. Uptake blockers increase synaptic concentrations of serotonin. Amphetamines enter monoamine neurons through the uptake transporter and interact with the vesicular transporter on synaptic vesicles to release neurotransmitter

into the cytoplasm. The neurotransmitter is then pumped out of the neuron into the synapse through the uptake transporter acting in reverse.

- **6.** Degradation. Phenelzine and tranylcypromine, both of which are effective for depression and panic disorder, block monoamine oxidase A and B (MAO_A and MAO_B). Moclobemide, effective against depression, is selective for MAO_A; selegiline, which has been used to treat Parkinson disease, is selective for MAO_B in low doses (5-HIAA, 5-hydroxyindoleacetic acid).
- B. Important sites of drug action at noradrenergic synapses.
- 1. Enzymatic synthesis. The competitive inhibitor α -methyltyrosine blocks the reaction catalyzed by tyrosine hydroxylase that converts tyrosine to DOPA. A dithiocarbamate derivative, FLA 63 (not shown), blocks the reaction that converts DOPA to dopamine.
- 2. Storage. Reserpine and tetrabenazine interfere with the transport of norepinephrine, dopamine, and serotonin into synaptic vesicles by blocking the vesicular monoamine transporter VMAT₂. The cytoplasmic neurotransmitter is degraded (see A. 6. below) and thus the neuron is depleted of neurotransmitter.
- 3. Presynaptic Receptors. Agonists at presynaptic receptors produce negative feedback on neurotransmitter synthesis or release. Clonidine is an agonist at α_2 adrenergic receptors, inhibiting norepinephrine (NE) release. It has anxiolytic and sedative effects and is also used to treat attention deficit hyperactivity disorder. Yohimbine is an antagonist at α_2 adrenergic receptors; it induces anxiety.
- 4. Postsynaptic Receptors. Propranolol is an antagonist at β_2 -adrenergic receptors that blocks many effects of the sympathetic nervous system. It is used to treat some forms of cardio-vascular disease but is commonly used to block anxiety during performance situations. Phenoxybenzamine is an agonist at α -adrenergic receptors.
- 5. *Uptake*. Certain tricyclic antidepressants, such as desipramine, and newer norepinephrine selective reuptake inhibitors (NRI) such as reboxetine, selectively block the norepinephrine transporter, thus increasing synaptic norepinephrine. Amphetamines enter monoaminergic neurons through the uptake transporter and interact with the vesicular transporter on synaptic vesicles to release neurotransmitter into the cytoplasm. The neurotransmitter is then pumped out of the neuron into the synapse through the uptake transporter acting in reverse.
- **6.** Degradation. At the postsynaptic neuron tropolone inhibits the enzyme catechol-O-methyltransferase (COMT), which inactivates norepinephrine (6a). Normetanephrine (NM) is formed by the action of COMT on norepinephrine. At the presynaptic neuron degradation by monoamine oxidase (MAO) is blocked by the monoamine oxidase inhibitors phenelzine and tranylcy-promine (6b), as described in Figure 63–5.

has recently revealed that a single intravenous dose of ketamine, which blocks NMDA-type glutamate receptors, produces antidepressant effects within hours and that these effects persist for a week. Ketamine was developed as a dissociative anesthetic, a drug that distances a person from the experience of his body and produces other cognitive disturbances. However, in adults it may also produce psychotic-like symptoms and euphoria, and so is an abused street drug. A drug with such a profile of action is not likely to prove useful as an antidepressant, but it has led to promising new avenues of research focused on signaling initiated by NMDA receptors.

Overall, evidence for direct involvement of monoamines in pathogenesis remains scant. A large number of genetic studies attempting to link polymorphisms in genes that influence serotonergic function have remained inconclusive.

Psychotherapy Is Effective in the Treatment of Major Depression

Nonpharmacologic treatments are also effective in the treatment of major depression. Short-term symptom-focused psychotherapies have been developed for depression and tested in clinical trials. The best-studied psychotherapy used against depression is cognitive-behavioral therapy, which is effective in the treatment of mild and moderately severe major depression and in dysthymic disorder. Cognitive-behavioral therapy focuses on identifying and correcting distorted negative interpretations of events and automatic negative thinking that may initiate or perpetuate the depressed mood (see Box 61–1).

An important challenge is to understand what happens in the brain in response to such specialized forms of learning as cognitive-behavioral therapy. For example, such therapies may alter the activity of brain structures thought to mediate negative emotion, such as the amygdala and anterior cingulate cortex. The use of brain imaging techniques to demonstrate such changes may eventually help identify those patients who are particularly amenable to cognitive therapy and track their therapeutic progress, and my even be useful in training and therapy as a form of biofeedback.

Electroconvulsive Therapy Is Highly Effective Against Depression

Although it still conjures up negative images in the popular imagination, electroconvulsive therapy (ECT) administered with modern anesthesia is medically safe and remains the single most effective intervention for

the acute treatment of serious major depression. It is also effective in both the depressed and manic phases of bipolar disorder. Electroconvulsive therapy is used when patients with major depression fail to respond to medication or when the patient is too debilitated to take medication.

Generally, six to eight treatments are given, most commonly on an outpatient basis, with unilateral lead placement. Bilateral placement can be used if unilateral is unsuccessful. Patients are anesthetized, and electrical stimulation is administered just to the degree that will produce electroencephalographic evidence of a generalized seizure. The major side effect is temporary memory impairment, with some retrograde amnesia. Amnesia is minimized by using unilateral lead placement and the lowest level of electrical stimulation needed. It is thought that electroconvulsive therapy increases the availability of biogenic amines in the brain, but its mechanism of action remains uncertain.

Motivated by the desire to improve on the therapeutic effects of ECT while diminishing its side effects, methods based on more focused forms of brain electrical stimulation are being explored. These include deep brain stimulation (DBS) using implanted electrodes and transcranial magnetic stimulation (TMS).

Bipolar Disorder Can Be Treated with Lithium and Several Drugs Initially Developed as Anticonvulsants

The discovery by John Cade in 1949 that lithium is effective in the treatment of mania initiated the modern era of psychopharmacology. In bipolar patients lithium not only treats acute episodes of mania but can also prevent recurrences of both mania and depression. It was thus the first "mood stabilizing" drug. Several drugs initially developed to treat epilepsy, such as valproic acid, were later shown to be effective in treating mania and in preventing recurrences of mania and depression.

The mechanism by which lithium stabilizes mood is not known. The two most promising ideas are based on lithium's ability to block enzymes involved in intracellular signaling pathways. Many neurotransmitter receptors indirectly activate phospholipase C through the G protein G_Q (eg, the α_1 -norepinephrine, 5-HT $_2$ serotonin, and several muscarinic acetylcholine receptors). Phospholipase C hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP $_2$) to liberate two second messengers (Figure 63–8). PIP $_2$ is normally synthesized from free inositol. Central neurons cannot obtain free inositol from plasma because of the blood-brain barrier. They therefore must either recycle inositol, which requires the generation of inositol phosphates

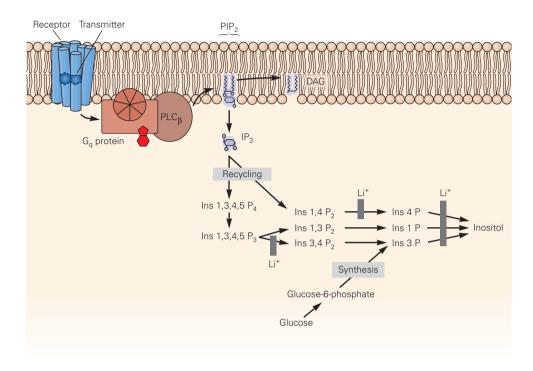

Figure 63–8 Lithium action on phosphatidylinositol pathways. A variety of neurotransmitter receptors are linked by the protein G_q (see Tables 63–3 and 63–4) to phospholipase C_{β} , which hydrolyzes phosphatidylinositol-4,5-biphosphate (PIP₂) to generate two second messengers, diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP₃). IP₃ releases Ca^{2+} from intracellular stores and subsequently is metabolized to forms that may not participate in neural signal transduction, including inositol 1,3,4,5-tetraphosphate (Ins 1,3,4,5 P₄). These are all metabolized to produce several inositol monophosphates, of which all are in turn metabolized by inositol monophosphate

phosphatase, an enzyme that is inhibited by therapeutic concentrations of lithium (Li⁺). De novo synthesis of inositol from glucose-6-phosphate also must pass through an inositol monophosphate intermediate. Thus in the presence of lithium the monophosphates derived from recycling of second messengers or from new synthesis cannot be dephosphorylated to yield free inositol. This should inhibit the ability of cells to regenerate PIP₂ and thus disrupt the second-messenger cascade. (Reproduced, with permission, from Nestler, Hyman, and Malenka 2009.)

by hydrolysis of phosphatidylinositols, or synthesize it from glucose-6-phosphate, a product of glycolysis.

Lithium inhibits several inositol phosphatases, including inositol-monophosphate-phosphatase, which is critical for the synthesis of the second messengers diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP₃) (Figure 63–8). As a result, lithium would appear to limit the ability of neurons to synthesize precursors of second messengers and therefore dampen the ability of neurons to fire at abnormally high rates. Alternatively, inositol depletion might alter gene expression that in turn would alter the response properties of critical neurons.

The second idea about how lithium stabilizes mood comes from the observation that lithium inhibits glycogen synthase kinase type 3 (GSK3), a critical enzyme in the Wnt signaling pathway (Figure 63–9). The Wnt signaling pathway plays important roles in

brain development (see Chapter 53). How inhibition of this pathway might treat mania remains unknown.

Valproic acid is an anticonvulsant that also stabilizes mood. It appears to facilitate the actions of GABA (γ -aminobutyric acid), the key inhibitory neurotransmitter in the brain, possibly by increasing GABA release. The mechanisms by which anticonvulsants might treat bipolar disorder and the question of whether the mechanisms are shared with lithium remain important but unanswered.

Whatever the molecular mechanisms of lithium or the anticonvulsants, it seems likely that mood stabilizers dampen the dynamics of mood regulatory systems. Mood is regulated by the external environment as well as internal inputs, including the internal hormonal milieu, immune modulators, and circadian controls (eg, both the serotonergic and noradrenergic

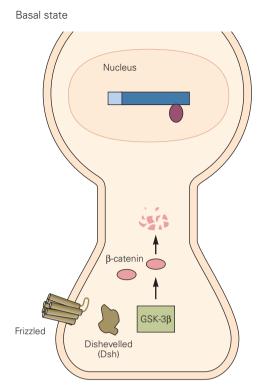

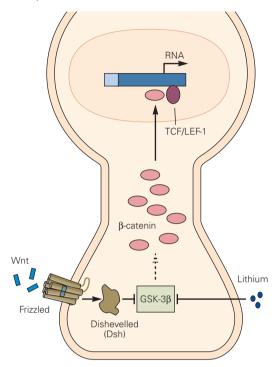

Figure 63–9 Lithium affects the Wnt signaling pathway. Wnt secretory proteins are involved in cell proliferation and differentiation. The Wnt protein was initially discovered as a critical molecule in *Drosophila* wing development but has been identified in the mammalian brain as well. Wnt binds receptors of the Frizzled family, initiating a signaling cascade to the nucleus that involves a cytosolic protein Dishevelled (Dsh) and glycogen synthase kinase 3β (GSK- 3β). Phosphorylation by GSK- 3β causes the degradation of another protein, β -catenin (left panel).

systems show diurnal variations closely coupled with the sleep-wake cycle). The coupling of these systems is complex, involving dynamic interactions that are still poorly understood. Understanding these interactions is likely to give insight into the pathological cycle of bipolar disorder.

Anxiety Disorders Stem from Abnormal Regulation of Fear

Fear is a complex physiological, behavioral, cognitive, and, in humans, subjective response to a threatening stimulus. It evolved as an adaptive response to real threats and is usually transient. Anxiety is a longer-lasting response to danger signals that can arise either from immediate circumstances that signal well-defined danger or from vague indications of

Therapeutic lithium

GSK-3 β is inhibited when Wnt binds Frizzled or when lithium is present in therapeutic concentrations, thus stabilizing β -catenin (right panel). When the level of β -catenin builds up, the protein translocates to the nucleus of the cell where it activates gene expression through a transcription complex TCF/LEF-1. Which genes might be induced by this pathway to stabilize mood is unknown. Interestingly, a Dsh knockout mouse exhibits abnormal social behavior and grooming. (Reproduced, with permission, from Nestler, Hyman, and Malenka 2009.)

ill-defined events that are thought to have adverse consequences.

Anxiety can be highly adaptive; arousal, vigilance, and physical preparedness increase the likelihood of survival in dangerous situations. However, because many situations lack clear signs of safety, anxiety can persist. When anxiety persists beyond genuine risk, or when it produces a response out of proportion to the possible threat, the result can be distressing and disabling. Anxiety is the core symptom in several common psychiatric disorders. In the United States 28.5% of the population suffer from one or more anxiety disorders over the course of their lifetimes.

Anxiety disorders are distinguished from each other by the nature, intensity, and time course of symptoms, patterns of familial transmission, precipitating factors, the role of external cues in triggering episodes, and the constellation of associated symptoms. In some

situations anxiety is not produced by a single eliciting stimulus but by an accumulation of cues. The currently recognized anxiety disorders are panic disorder, post-traumatic stress disorder, generalized anxiety disorder, social anxiety disorder (also called social phobia), simple phobias, and obsessive-compulsive disorder.

Panic disorder. The cardinal symptom of panic disorder is the unexpected panic attack consisting of a discrete period of intense fear accompanied by somatic symptoms such as palpitations, shortness of breath, sweating, paresthesias, and dizziness, and by a powerful fear of losing control or of dying (Table 63–5). Panic disorder is diagnosed when panic attacks recur and give rise to anticipatory anxiety about future attacks. People with panic disorder might restrict their lives progressively to avoid situations or places in which attacks occur or from which they might not be able escape should they experience an attack. It is common for patients to avoid crowds, bridges, and elevators; some individuals eventually stop leaving home altogether. A generalized phobic avoidance is called *agoraphobia*.

Post-traumatic stress disorder. Post-traumatic stress disorder (PTSD) follows an experience of severe danger or injury. First recognized in soldiers during World War I after combat trauma, it also occurs after civilian

Table 63-5 Symptoms of a Panic Attack

A discrete period of intense fear or discomfort in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes:

Palpitations, pounding heart, or accelerated heart rate Sweating

Trembling or shaking

Sensations of shortness of breath or smothering

Feeling of choking

Chest pain or discomfort

Nausea or abdominal distress

Feeling dizzy, unsteady, lightheaded, or faint

Derealization (feelings or unreality) or depersonalization (being detached from oneself)

Fear of losing control or going crazy

Fear of dying

Paresthesias (numbness or tingling sensations)

Chills or hot flushes

traumas such as violent assaults or serious accidents. It is characterized by emotional numbness to ordinary stimuli, punctuated by painful reliving of the traumatic episode, often initiated by sounds, images, or odors that trigger highly charged memories of the circumstances in which the trauma occurred. For example, a Vietnam War veteran with PTSD might experience intense symptoms after hearing a traffic helicopter pass overhead (recalling the heavy use of assault helicopters in that war). It is also characterized by disturbed sleep that can include nightmares, and by hyperarousal, such as an exaggerated startle response.

Generalized anxiety disorder. This disorder is characterized by chronic (months-long) worry and vigilance that is not warranted by circumstances. This worry is accompanied by physiological disturbances such as heightened sympathetic nervous system arousal (evidenced by an increase in heart rate) and by motor tension.

Social anxiety disorder. This disorder is characterized by a persistent fear of social situations or performance situations that expose a person to the scrutiny of others. The patient has an intense fear of acting in a way that will prove humiliating. Stage fright is a form of social anxiety that is limited to special circumstances, such as public speaking. Generalized social anxiety, as its name implies, involves adverse responses to most social situations and can therefore prove quite disabling.

Simple phobias consist of intense, excessive fear of specific stimuli, such as snakes, spiders, or height.

Obsessive-compulsive disorder. Obsessive-compulsive disorder (OCD) is characterized by obsessions (intrusive, unwanted thoughts) and compulsions (performance of highly ritualized behaviors intended to neutralize the negative thoughts and emotions resulting from the obsessions). The person experiences the obsessions as foreign and unwanted. Attempts to resist the urge to perform the compulsive acts result in high levels of anxiety. Typical symptom patterns are repetitive hand washing to neutralize fears of contamination (sometimes hours a day to the point of skin damage), or repeatedly checking the front door to see that it is locked.

Although current classifications of psychiatric disorders, including *DSM-IV*, place OCD among the anxiety disorders, family studies and imaging studies suggest that the disorder may share risk factors and dysfunction of striatal circuits with Tourette disorder, which is characterized by motor tics (involuntary, rapid movements) as well as vocal tics—grunts, noises, obscenities—and is often accompanied by obsessive-compulsive symptoms. Additional evidence for primary problems in striatal circuits, rather than the amygdala circuits implicated in other anxiety disorders, comes from the study of Sydenham chorea,

a movement disorder that can result from acute rheumatic fever. Interestingly, many patients with Sydenham chorea experience transient OCD-like symptoms. Sydenham chorea results from antibodies developed in response to a streptococcal infection, and the antibodies have been shown to bind to neurons in the striatum. OCD can be treated with high doses of selective serotonin reuptake inhibitor and by psychotherapy aimed at stopping intrusive thoughts and compulsive rituals.

Anxiety Disorders Have a Genetic Component

Panic disorder, generalized anxiety disorder, phobias, and OCD all run in families. First-degree relatives of individuals with panic disorder have a significantly greater risk of panic disorder than the general population or the first-degree relatives of unaffected control subjects.

Twin studies have concluded that panic disorder, generalized anxiety disorder, and probably phobias are explained to a large extent by genes. Twin studies also suggest overlapping genetic risk factors for depression and generalized anxiety disorder, which helps explain the observation that these two disorders often occur together.

In post-traumatic stress disorder genes appear to act in two important ways. They influence (1) the risk of developing the disorder after exposure to traumatic events and (2) the likelihood of individuals exposing themselves to dangerous situations.

Animal Models of Fear May Shed Light on Human Anxiety Disorders

Because many responses to fearful stimuli are conserved across mammalian species, animal models are potentially relevant to human disorders. In addition, because stimuli that elicit fear and anxiety can be readily produced in the laboratory, animal models are amenable to study. Studies using animal models have focused on two general classes of fear: innate fear and learned fear.

Studies of innate or instinctual fear exploit the natural tendencies of rats and mice to avoid open spaces or other situations that expose them to predators (Figure 63–10). Studies of learned or conditioned fear exploit the ability of rodents and other animals to form powerful associations between previously neutral cues and temporally linked danger. As described in Chapter 48, studies using these animal models have led to the outline of an amygdala-based fear circuitry that mediates defensive behaviors and appropriate physiologic responses to danger. They have been useful in designing noninvasive studies of human subjects with anxiety disorders, and as screens for anxiety-reducing drugs and genetic mutations that influence fear.

Our growing understanding of fear circuitry has generated testable hypotheses about the pathophysiology of

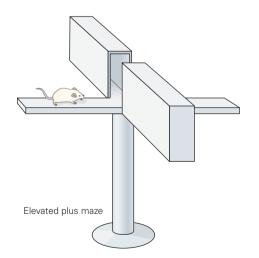

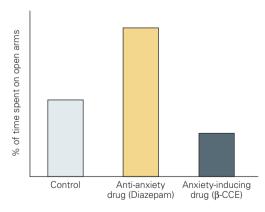

Figure 63–10 The effects of anxiety-reducing drugs can be tested on rodents in the elevated plus maze. The apparatus has two intersecting arms, one enclosed and the other open. A rat or mouse is placed at the intersection and the time spent on the open or enclosed arms is measured. Rodents normally prefer the closed arm. Rodents given benzodiazepine drugs,

such as diazepam, which reduce anxiety in humans, spend more time in the open arm. Rodents given the benzodiazepine inverse agonist β -carboline (β -CCE), which strongly induces anxiety in humans, spend less time in the open arm. (Reproduced, with permission, from Nestler, Hyman, and Malenka 2009.)

human anxiety disorders such as post-traumatic stress disorder. For example, fear conditioning occurs normally in humans and is usually adaptive. By learning cues that signify danger and developing efficient responses, an individual minimizes future risk of harm. The central abnormality in post-traumatic stress disorder appears to be fear conditioning that is excessive, such that later minor cues are able to elicit fear responses. This dysregulated fear response alters other cognitive, emotional, and physiological responses. By mechanisms that are not yet well understood, it may alter basal levels of arousal, leading to exaggerated startle responses and disordered sleep. Other aspects of post-traumatic stress disorder, such as emotional numbing, are more difficult to model in experimental animals.

The unexpected panic attack—the hallmark of panic disorder—may represent a "false alarm" in which the fear circuitry is activated in the absence of a threat. Whether such abnormal activation originates from the fear circuitry itself or elsewhere in the nervous system is not known. Panic attacks can be produced in susceptible people by increasing partial pressure of carbon dioxide (PCO₂) in their blood or administering caffeine or drugs, which increase sympathetic outflow. Although these observations suggest a low threshold for activating the fear circuitry in persons with panic disorder, we do not yet understand the neurophysiologic mechanisms that trigger spontaneous panic attacks.

Panic attacks can be a source of fear conditioning. Initially, panic attacks are usually spontaneous, with no obvious relationship to the immediate context or environmental stimuli. However, environmental cues experienced in conjunction with a panic attack can become fear-associated stimuli. Later, these cues can trigger severe anticipatory anxiety or even a full panic attack.

With simple phobias and social anxiety the fear circuitry may be activated by cues that ordinarily signal very limited, if any, danger, such as risk of embarrassment. The experience can lead to avoidance of the cues. A person with a phobia of air travel might limit travel to surface transportation, and a person with stage fright might alter career plans to avoid public speaking.

Neuro-imaging Implicates Amygdala-Based Circuits in Human Fear and Anxiety

The understanding of the neural circuitry underlying fear and anxiety in animal models has guided neuroimaging studies of humans. In healthy subjects the amygdala is activated in response to stimuli that reliably induce fear, such as faces portraying fear, as well as during fear conditioning. In a functional magnetic resonance imaging (fMRI) study of normal volunteers the presentation of a face portraying fear activated the dorsal subregion of the amygdala; this region contains what is thought to be the amygdala's main output nucleus, the central nucleus. When the same faces were shown only briefly to these subjects, followed by a neutral face (referred to as backward masking), the subjects did not report awareness of having seen the fearful face. Yet they exhibited physiological signs of fear (activation of the sympathetic nervous system). This test paradigm activates the basolateral subregion of the amygdala (which contains inputs from the thalamus and cerebral cortex) in healthy subjects similar to that of subjects with anxiety disorders (Figure 63–11).

Functional neuroimaging has also revealed heightened activity in the amygdala in specific anxiety disorders, including social anxiety disorder and posttraumatic stress disorder. In individuals with social anxiety disorder the increase in activity is induced by images of fearful faces; in individuals with posttraumatic stress disorder it is induced by narratives that are reminiscent of their trauma.

Structural imaging has also been used to study anxiety disorders. The most often replicated structural finding is diminished hippocampal volume in individuals with depression or post-traumatic stress disorder. Until longitudinal studies are performed, it is not clear whether a small hippocampus is a risk factor for post-traumatic stress disorder or a result of the disorder.

Anxiety Disorders Can Be Treated Effectively with Medications and Psychotherapy

Cognitive-behavioral therapies designed for specific anxiety disorders have proved as effective as medication in the treatment of anxiety disorders. For example, a person with cue-elicited anxiety, whether a simple phobia, phobic avoidance resulting from panic disorder, or social anxiety disorder, is coached to confront the phobic stimulus with adequate support and a new cognitive schema for coping with the fear. For many patients a combination of medication and cognitive-behavioral therapy may prove necessary.

Among the medications used for various anxiety disorders, drugs that were initially developed as antidepressants have proven highly efficacious and are the drugs of choice. The selective serotonin reuptake inhibitors are most widely used because they are easily tolerated. Simple phobias are best treated with cognitive-behavioral therapy rather than medication. The response of obsessive-compulsive disorder to treatment differs from those anxiety disorders in which amygdala-based

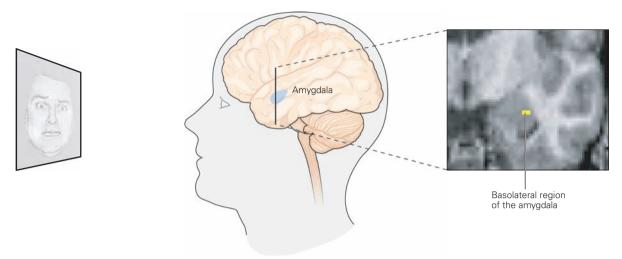

Figure 63–11 Amygdala activation in response to a masked presentation of a fearful stimulus. A human subject observes projected images while being scanned by magnetic resonance imaging. When a fearful face is presented for a very brief time followed by presentation of a neutral face (a protocol called

backward masking), the subject is not consciously aware of the fearful face. Under these conditions the basolateral region of the amygdala predicts individual differences in trait anxiety in healthy subjects similar to those found in patients with anxiety disorders. (Reproduced, with permission, from Etkin et al. 2004.)

fear circuitry is thought to be the primary abnormality. Obsessive-compulsive disorder responds only to serotonin selective drugs at higher doses. Medications are generally combined with cognitive-behavioral therapy specially designed to inhibit compulsive behaviors.

Another class of drugs, the benzodiazepines, are occasionally used for generalized anxiety disorder, whereas higher doses are used for panic disorder. However, existing benzodiazepines can cause sedation; indeed, they are also used as hypnotics, and can degrade cognitive function. Moreover, benzodiazepines can cause dependence (as evidenced by worsened, so-called rebound anxiety) and insomnia when drugs are discontinued. In some individuals they can produce addiction (see Chapter 49). An advantage of the benzodiazepines is they react rapidly following a single dose, in contrast to the antidepressants, which can take weeks to become effective. Overall, they are second-line treatments to the selective serotonin reuptake inhibitors and other antidepressants, often used temporarily until the response to antidepressants takes effect.

The benzodiazepines produce their therapeutic effect by enhancing the inhibitory action of GABA at GABA_A receptors. This receptor is ionotropic and selective for Cl⁻. It is a pentamer, organized like barrel staves around an aqueous pore (Figure 63–12). Allosteric binding of benzodiazepine modifies the receptor complex, increasing the affinity of the GABA binding site for GABA. As a result, GABA-activated Cl⁻ channels open more frequently, enhancing the hyperpolarizing effect

of GABA on the neuron. The sedative barbiturate drugs also bind the GABA_A receptor complex, but at a site near the Cl⁻ channel. Barbiturates increase not only the affinity of the receptor for GABA but also channel open time, creating a greater risk of excessive central nervous system depression than is seen with benzodiazepines.

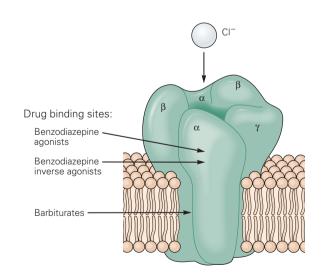

Figure 63–12 The GABA_A receptor complex. The GABA_A (γ-aminobutyric acid A) receptor is a pentamer arranged to form a Cl⁻ channel. In addition to the neurotransmitter GABA, the receptor binds several important drugs, including benzodiazepines and barbiturates, at physically separate sites.

An Overall View

Mood and anxiety disorders have long been misunderstood, even to the point that affected individuals can become objects of stigma. Because mood and anxiety disorders have a far greater impact on disability than on mortality (despite the risk of suicide), these disorders have too often been given low priority by healthcare systems.

These unfortunate circumstances are beginning to change. Modern epidemiological and economic research has documented the enormous burden created by these disorders, which tend to begin early in life and to interfere with learning in young people and the ability to work in adults. Increased scientific understanding has also made a difference.

Although there is still a long way to go before we understand fully the neural basis of these disorders or the genetic, developmental, and environmental risk factors that give rise to them, there is little doubt that mood and anxiety disorders are real disorders of the brain. For example, compelling hypotheses concerning the neural circuits underlying anxiety disorders have been put forth and are being tested, and neuro-imaging has provided important leads in the study of mood disorders.

The existing treatments for chronic mood and anxiety disorders are generally not curative. However, existing medications and cognitive-behavioral therapies can markedly improve symptoms, even to the point of remission for many individuals. The study of mood and anxiety disorders is a challenging frontier for neural science, but a challenge with very significant rewards for human health.

An Overall View

URING THE PAST CENTURY "MENTAL RETARDATION" was broadly used to label a variety of cognitive impairments that were linked to prenatal or early postnatal brain abnormalities. Some subgroups with easily identifiable physical features, such as Down syndrome, were recognized early on. In recent years syndromes that result from genetic anomalies but do not express obvious physical features, such as fragile X syndrome, have also been delineated.

Common to all of these disorders are mental impairments that persist throughout life, hampering

development and learning, hence the terms "neurodevelopmental disorder" and "learning disability." Generally speaking, even if all mental functions seem to be affected, some tend to be more affected than others. This differential vulnerability gives interesting clues about the different origins and developmental time course of specific mental functions in normal development.

In this chapter we focus on autism and briefly consider Down syndrome, fragile X, and other neurodevelopmental disorders with a known genetic basis. Autism is especially interesting because it impairs brain functions that are highly sophisticated in human beings: social awareness and communication. Autism is also an exemplar of many psychiatric disorders: there is a striking range in severity of symptoms, an impressive heterogeneity of comorbid conditions, and no clear cut neuropathology. It is likely that autism will ultimately be viewed as a class of disorders each with different etiologies that include genetic and environmental factors and their interaction.

Autism Has Characteristic Behavioral Features

Autism has probably always been with us, but it was identified and labeled only in 1943 by Leo Kanner and by Hans Asperger in 1944. Where were the autistic people in the past? Rare historical documents suggest that some may have been valued as eccentrics or holy fools, but the majority were probably considered to suffer constitutional mental deficiency.

Today clinicians and researchers think of autism as a spectrum of disorders with three common diagnostic features, each showing a great deal of variability among individuals: impaired social interaction, impaired verbal and nonverbal communication, and restricted or circumscribed interests with stereotyped behaviors. The label "Asperger syndrome" is often used for individuals who exhibit the typical features of autism but have high verbal ability and no delay in language acquisition.

Autism and related disorders affect approximately 1% of the population, a far higher frequency than was previously recognized. Whether this reflects a better understanding and recognition of the range of disorders that actually belongs in this category or an actual increase in incidence is not entirely clear. The possibility that this increase is due to immunization or any simple environmental factor has been largely eliminated. Some studies indicate that the sperm of older fathers increases the incidence of autism as it does for schizophrenia. Risk also goes up with the age of the mother. As we shall see below, up to 10% of children with autism carry a genetic defect that results from a copy number variation, a mutation that arises in the germline.

Classification today is based on the three diagnostic criteria described above, which are more inclusive than those used in the earliest descriptions of the disease. Boys outnumber girls by 4 to 1, and by approximately 8 to 1 in cases of autism without intellectual disability. Although autism can occur in people with a high IQ, more than half the individuals with autism suffer from intellectual disability (defined as an IQ below 70). By definition, autism should be detectable before the child is 3 years old. Autism occurs in all countries and cultures and in every socioeconomic group.

Although autism is clearly a disorder that affects the brain, there are as yet no diagnostic biological markers and therefore diagnosis is based on behavioral criteria. Because behavior is highly changeable during development and depends on a number of factors, such as age, environment, social context, and availability and duration of remedial help, no single behavior could ever be diagnostic.

Some parents of an autistic child are aware that something is not quite right with their child from an early age. Other parents report that their babies first developed typically and then regressed in their development during the second year of life. A prospective study of siblings at genetic risk for autism showed that at age 6 months infants at genetic risk and later diagnosed autistic did not differ from those who were typically developing on measures of social interaction, such as gaze to faces, social smile, and

vocalizations to others. However, differences from typically developing children increasingly emerged and were significant by 1 year of age. One of the earliest signs, near the end of the first year, is that the baby does not turn when called by name. Other early signs include the lack of preference for people over objects, and repetitive use of objects, such as spinning, and unusual visual exploration.

Beginning at approximately 18 months of age several other signs become clear. Most children with autism do not automatically direct their attention to the person or object that is the focus of other people's attention. Children with autism often fail to use pointing or other gestures to direct the attention of other people. They also fail to engage in ordinary makebelieve play. Later, signs of delayed and abnormal language development are evident, with echoing of other people's speech (echolalia) and the use of idiosyncratic expressions. By the age of 3, typical cases of autism can be diagnosed reliably on the basis of this constellation of social and communication impairments, and rigid and repetitive behavior and interests. In cases where there is neither intellectual disability nor language delay (Asperger syndrome), diagnosis is typically not made until school age.

Like other neurodevelopmental disorders, autism is a lifelong disorder. Autism is not progressive, however. On the contrary, special educational programs and professional support often lead to marked improvements in behavior with age. The understanding and use of language by people with autism is quite variable. Even in individuals of high ability, language remains literal and conversational skills are lacking, as evident in poor turn-taking and poor understanding of irony. Most people with autism continue to find social situations difficult and are hampered in their ability to make friends or sustain lasting relationships.

A preference for routines and restricted behavior patterns remains throughout life, although the nature of obsessions and interests often undergo marked changes. In early childhood an individual may be drawn to shiny pieces of metal, in later childhood collect light bulbs, and in adulthood obsessively construct a novel dictionary. Hypersensitivity to touch, taste, sound, or vision is frequently mentioned in personal accounts and appears to play a role in restricting behavior by creating strong avoidances or preferences. Unfortunately, no neurobiological insight into these alterations in sensory function has yet emerged. People with autism are commonly susceptible to a variety of co-morbid psychiatric problems, particularly anxiety and depression. Nevertheless, reasonably good

adaptation is possible when the environment is stable and highly structured.

There Is a Strong Genetic Component in Autism

Convincing data that autism has a strong genetic component come from studies of monozygotic twin pairs, who have identical genes. These studies show anywhere from 60% to 91% concordance of autism. The range is broad in part because some studies consider only the most serious forms of autism, whereas others consider the full spectrum of autism-like disorders. Dizygotic twins, in contrast, have been estimated to have 10-30% concordance when the full autism spectrum is considered. If a woman has one child with autism, the risk that a second child will have autism increases approximately 20-fold. Approximately 20% of siblings of a child with autism may also have autism. The risk increases if the second child is a male or if two prior children have disorders on the autism spectrum.

These family studies indicate that autism is not generally the result of mutations in a single gene but rather variation in many genes, giving rise to a complex pattern of inheritance. As in other polygenic disorders, it is likely that the genes responsible are not the same genes in all individuals but that different combinations are drawn from a larger pool of predisposing genes. This heterogeneity has made the identification of specific genes difficult.

Despite the difficulties, genomic regions have been implicated on several chromosomes. Of particular interest are mutations in two genes on the X chromosome in two sibling pairs with either autism or Asperger syndrome. These genes encode neuroligins, postsynaptic cell adhesion proteins important in synapse formation. These observations are intriguing because they are X-linked genes and may explain the male preponderance. The neuroligin discovery has recently been supported by a study of mice harboring mutations similar to the human mutations. These mice show impaired social interactions and, as a neural correlate, increased inhibitory synaptic transmission.

In addition to conventional mutations in specific genes, copy number variation has emerged as a potentially important genetic mechanism in autism. Copy number variation describes genomic deletions and duplications of pieces of a chromosome involving up to 100 consecutive genes on a chromosome. These deletions and duplications have recently been appreciated

as a significant source of genetic variation in humans. Although copy number variants are almost always inherited, recent studies suggest that 10% of autistic patients carry a de novo gene copy number that neither parent carries. These are caused not by more common conventional mutations of discrete genes but by sporadic mutations of genomic structure in the germline in the cells that give rise to sperm and ova. Thus copy number variations may play an important role in autism (and other disorders) and perhaps explain the difficulties encountered in identifying autism-susceptibility genes.

Even though heritability, or the proportion of the phenotypic variance due to genetic factors, is very high for autism, environmental factors likely also play an important role, although no specific environmental factors have been conclusively identified. Infections by viruses (such as rubella, measles, influenza, herpes simplex, and cytomegalovirus) may contribute to the etiology of autism and perhaps represent environmental cues. The possibility that a genetic defect alters features of brain development by affecting the immune system is receiving greater attention. There is substantial evidence that mediators of immune functions such as cytokines and chemokines also play a role in brain development including synaptogenesis. Given the complexity of autism and its various forms, it is likely that a variety of etiologies will ultimately be discovered, some purely genetic, others that depend on genetic risk factors coupled with environmental factors, and some purely environmental causes.

Autism Has Characteristic Neurological Abnormalities

If autism is a developmental disorder of the brain, what parts of the nervous system are most severely affected? Research in this area is still in its infancy and no comprehensive picture of the neuropathology of autism is yet available. In fact, for a disorder with such a profound impact on the life of an individual, the brain, at least at a superficial level, looks relatively normal. However, more detailed quantitative analyses have begun to demonstrate consistent alterations in the size and time course of development of particular brain regions.

The first magnetic resonance imaging (MRI) studies of autism in the mid-1980s focused on the cerebellum and suggested that hypoplasia of the cerebellar vermis was characteristic of autism. These findings,

however, have generally not been replicated. Other brain regions that have been found to be abnormal in autism include the cerebral cortex (although the salient portion of the cerebral cortex varies from study to study), medial temporal lobe structures such as the amygdala and hippocampus, and the corpus callosum (Figure 64–1).

The notion that cortical development may be altered in autism arose from clinical observations that before age 2 the head circumference of children with autism is often larger than typically developing

controls. Approximately 20% of individuals with autism have unusually large heads (macrocephaly). These data would suggest that a large head and thus increased brain size might be a common, although by no means universal, feature of autism. There is, however, increasing evidence that an abnormal time course in development, not the outcome of brain development, is diagnostic of autism.

Several research groups have gathered provocative evidence for precocious growth of the brain, and particularly of the frontal lobe, during the first few

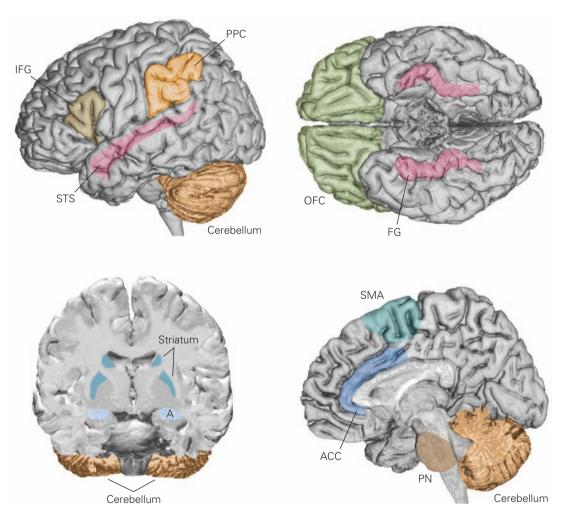

Figure 64–1 Brain areas implicated in the three core deficits characteristic of autism: impaired social interaction, impaired language and communication, and severely restricted interests with repetitive and stereotyped behaviors. Areas implicated in social deficits include the orbitofrontal cortex (OFC), the anterior cingulate cortex (ACC), and the amygdala (A). Cortex bordering the superior temporal sulcus (STS) has been implicated in mediating the perception that a living

thing is moving and gaze perception. Face processing involves a region of the inferior temporal cortex within the fusiform gyrus (FG). Comprehension and expression of language involve a number of regions including the inferior frontal region, the striatum, and subcortical areas such as the pontine nuclei (PN). The striatum has also been implicated in the mediation of repetitive behaviors. A number of imaging and postmortem studies have indicated that the cerebellum may also be pathological in autism.

years of life of autistic children. Most studies show that at birth the brains of children with autism are either of normal size or perhaps slightly smaller than typically developing children and this is true again in adulthood. Clearly, the development of the brain is a precisely orchestrated process; if one or more brain regions develop out of sequence, patterns of brain connectivity and thus brain function could be seriously disturbed.

Beyond the cerebral cortex, other brain regions also show abnormal development. Perhaps most striking is the amygdala, a region of the temporal lobe that is involved in the detection of dangers in the environment and in modulating some forms of social interaction (see Chapter 48). Interestingly, in typically developing boys the amygdala develops over an unusually long period, increasing in size by nearly 40% between the ages of 8 and 18 years. The rest of the brain actually decreases in size during this same time period by approximately 10% because of refinement of connectivity and function. For boys with autism the amygdala reaches adult size by eight years of age. Thus whatever refinement of connectivity takes place in typically developing preadolescent and adolescent children may not occur in boys with autism.

Many studies have gone beyond simply evaluating the volume of the brain or brain regions and have analytically broken down a region of the brain into compartments representing grey matter and white matter. Alterations in white matter volume may actually be a more sensitive indicator of pathology in autism than grey matter differences. In fact, some researchers have proposed that the enlarged brain volume that has been reported in young children with autism can be accounted for, in large part, by disproportionate increases in white matter volume. Thus some studies have found a larger volume of white matter in boys with autism aged 2 to 3 years compared to controls. Interestingly, this difference was not found in adolescence, further evidence of an abnormality of early development.

As these studies illustrate, autism is not a disorder that affects a single brain region. The amount and kind of brain pathology in a particular individual may depend on whether the etiology is more genetic or environmental. Finally, the pathology of autism may not be apparent in the mature size and shape of the brain but in the time course of development of both the structure and connections of the brain.

The picture of the neuropathology of autism at a microscopic level is also not clear. This is in part because of the paucity of brains available for analysis. To date fewer than 200 brains have been subjected to microscopic analysis, and only a small fraction of these have undergone quantitative analysis. Another problem is the co-morbid occurrence of epilepsy. Approximately 30% of individuals with autism also have seizure disorders, and seizures damage the amygdala and many of the other brain regions that have been implicated in autism.

One reasonably consistent finding in autism has been the lower number of Purkinje cells in the cerebellum. Gaps in the orderly arrays of Purkinje cells are noticeable when using neural stains that mark cell bodies. Whether this reduction in cell number is because of autism, epilepsy, or the co-occurrence of both disorders is not clear. It is also not clear whether reduced numbers of Purkinje cells are characteristic of autism or a more general finding in neurodevelopmental disorders. Cerebellar alterations have been found in cases of idiopathic intellectual disability, Williams syndrome, and many other childhood disorders. A few cases of alterations of brain stem nuclei that are connected to the cerebellum, such as the olivary complex, have also been reported.

Microscopic abnormalities have also been observed in the autistic cerebral cortex, including defects in the migration of cells into the cortex, such as ectopias, nests of cells in white matter that failed to enter the cortex. It has also been proposed that the columnar organization of the autistic cortex is abnormal. These provocative findings are awaiting confirmation in larger studies using quantitative strategies. Finally, one study found fewer neurons in the mature amygdala of people with autism. Because this study was carried out with individuals that did not have co-morbid epilepsy, the change in the amygdala looks to be a real component of autistic neuropathology. It raises the possibility that autism may have a neurodegenerative component to its pathology.

There Are Distinctive Cognitive Abnormalities in Autism

Social Communication Is Impaired: The Mind Blindness Hypothesis

One cognitive theory of social communication, termed *theory of mind*, postulates that humans have a particularly well-developed ability to attribute mental states to others in an intuitive and fully automatic fashion. Watching a young man surreptitiously trying to open a car door without a key, you instantly understand that he believes he can break in while being unobserved, and expect him to run away as soon as he realizes someone is watching. Thus you explain and predict his

behavior by inferring his mental states (desires, intentions, beliefs, knowledge). This so-called mentalizing ability is thought to have an identifiable biological basis and to depend on a dedicated brain mechanism. Further, it is postulated that this mentalizing mechanism is faulty in autism, with profound effects on social development.

It is now generally agreed that certain social insights typical of humans depend on the capacity to mentalize spontaneously. Spontaneous mentalizing allows us to appreciate that different people have different thoughts and that thoughts represent internal functions of the mind that are different from external reality. From an evolutionary point of view, the capacity to mentalize is extremely advantageous. It enables us to predict what other people are going to do next by "reading" their minds. It helps us to deceive and outsmart others, but also to teach and persuade, thus facilitating social and cultural learning.

The inability to mentalize, or "mind blindness," was first tested in autism with a simple puppet game, the Sally-Anne test. Young children with autism, unlike those with Down syndrome and unlike typically developing four-year-olds, cannot predict where a puppet will first look for an object that was moved while the puppet was out of the room. They are not able to imagine that the puppet will "think" that the object will be where the puppet had left it (Figure 64–2). Many autistic children eventually do learn to pass this task, but on average with a 5-year delay. Mentalizing acquired so slowly remains effortful and error-prone even in adulthood.

At the same time, young children with autism show excellent appreciation of physical causes and events. For instance, the child who is incapable of deceiving a character (by falsely telling him that a box is locked), is quite capable of locking the same box to prevent the thief from stealing its contents.

Variations of the Sally-Anne test and other mentalizing tasks have been used with children and adults with autism and Asperger syndrome since the mid 1980s (Figure 64–3). Compared to people with low-functioning autism, people with Asperger syndrome do much better when tested on mentalizing tasks, but they still show subtle difficulties. Whereas they solve many of these tests through effortful mentalizing, they show a lack of automatic mentalizing. This can be assessed by eye gaze anticipation. In contrast, there is some evidence that typically developing infants as young as 7 months show spontaneous mentalizing, and there is wide agreement that this automatic ability is well established from the second year of life.

Functional neuroimaging studies have scanned the brains of healthy subjects while they are engaged in tasks that necessitate thinking about mental states. A wide range of tasks using visual and verbal stimuli has been used in these studies. The results indicate that mentalizing is associated with the activation of a network of specific brain regions.

In one positron emission tomography (PET) study healthy adults viewed silent animations of geometric shapes. In some of the animations the triangles move in scripted scenarios designed to evoke mentalizing (for example, triangles tricking each other). In other animations the triangles move randomly and do not evoke mentalizing. Comparison of the scans made while subjects viewed the two types of animations reveals a specific network of four brain centers involved in mentalizing (Figure 64–4). Confirming the earlier PET study, more recent fMRI studies using the same animations also showed that in autism this network has reduced activation and weaker connectivity between its components.

One component of this network, the medial prefrontal cortex, is a region thought to be involved in monitoring one's own thoughts. A second component, in the temporoparietal region of the superior temporal lobe, is known to be activated by eye gaze and biological motion. Patients with lesions in this area in the left hemisphere are unable to pass the Sally-Anne test. The third region involves the amygdala, which is involved in the evaluation of social and nonsocial information for indications of danger in the environment. The fourth region involves the inferior temporal region, which is known to be involved in the perception of faces. All these components have been implicated in brain abnormalities in autistic individuals.

Other Social Mechanisms Contribute to Autism

The mind blindness hypothesis attributes all impairments in social communication to an inability to imagine the mental states of others. It has thus been influential as an example of how a specific cognitive deficit that explains a range of behavioral symptoms can arise from a neurophysiological or anatomical abnormality in specific networks of the brain.

The absence of preferential attention to social stimuli and mutual attention are widely acknowledged as early signs of autism. However, these may be distinct problems independent of mentalizing, given that mutual attention normally appears toward the end of the first year when signs of mentalizing are still sparse. Researchers have been considering the possibility

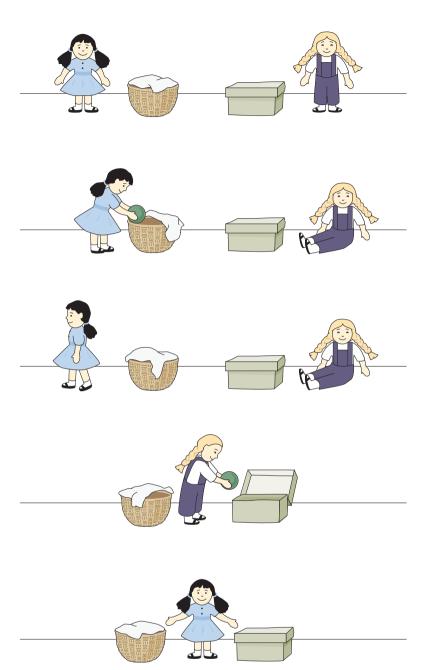

Figure 64–2 The Sally-Anne test. This first test of the "theory of mind" begins with a scripted performance using two dolls. Sally has a basket; Anne has a box. Sally puts a ball into her basket. She goes for a walk and leaves the room. While Sally is outside, naughty Anne takes the ball out of the basket and puts it into her box. Now Sally comes back from her walk and wants to play with her ball. Where will she look for the ball, the basket or the box? The answer, the basket, is obvious to most typically developing 4-year-olds but not to autistic children of the same or even higher mental age. (Adapted with permission, from Axel Scheffler.)

that a specific neural mechanism underlies attention to social stimuli, such as faces, voices, and biological motion. From birth normal infants prefer to attend to agents rather than other stimuli. An absence of this preference could lead to an inability to understand and interact with others. In favor of this hypothesis, researchers found that the gaze of individuals with autism is markedly abnormal when watching social scenes. One study found that autistic individuals fixate

on people's mouths instead of the normal preference for eyes (Figure 64–5).

Imaging experiments have compared brain activity in autistic and normal subjects while they watch agents, their movements, their faces or voices. In these studies evidence has been accumulating in support of the idea that autistic individuals show atypical perception of eye movements, facial expressions, body gestures, and actions. This evidence implicates

A Mentalizing required

B Mentalizing not required

Figure 64–3 Examples of cartoons used in imaging studies of "mentalizing." Participants were asked to consider the meaning of each picture (silently) and then to explain them. In a functional magnetic resonance imaging (fMRI) study normal adults passively viewed cartoons that require mentalizing versus those that do not. A characteristic network of brain regions is activated in each subject (see Figure 64–4). (Reproduced, with permission, from Gallagher et al. 2000.)

the superior temporal sulcus region, a region of the brain that is known to have a role in the perception of intention of actions. In addition, frontal and parietal attentional brain systems that facilitate orientation to social stimuli appear to exert less top-down control in autism.

People with Autism Show a Lack of Behavioral Flexibility

Repetitive and inflexible behavior in autism may reflect abnormalities in the executive functions of the frontal lobe, a wide array of higher cognitive processes that includes the ability to disengage from a given task, to inhibit inappropriate responses, to plan and manage sequences of deliberate actions by staying on task, keeping multiple task demands in working memory, monitoring performance, and shifting attention from one task to another.

Even autistic individuals with normal or superior IQ have problems in planning, organizing, and flexibly switching between behaviors. Both low- and

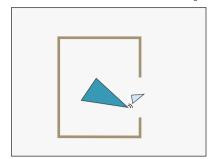

high-functioning individuals are stumped when asked to suggest different uses of one object such as a hand-kerchief (used to block a sneeze, to wrap loose objects, etc.). Flexible thinking is also poor in patients with acquired damage to the frontal lobe. In autism lack of flexible thinking appears to relate to a lack of behavioral flexibility in everyday life.

Difficulties in executive functioning are characteristic of other neurodevelopmental disorders: attention-deficit/hyperactive disorder, phenylketonuria, Tourette syndrome, dyslexia, and dyspraxia. For example, attention deficit hyperactive disorder is characterized by poor inhibitory control, whereas autism is characterized by poor flexibility, generativity, and planning. How the neural mechanisms underlying each of these difficulties differ is as yet unclear.

Some People with Autism Have Special Talents

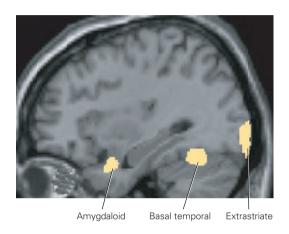

One of the most fascinating features of autism is the existence of so-called "islets of ability", in at least 10% of the cases, in music, art, calculation, or memory.

Frame from animation that elicits mentalizing

Medial prefrontal cortex

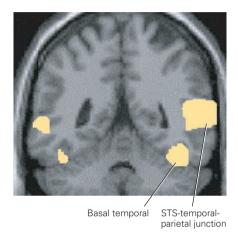

Figure 64–4 The mentalizing system of the brain. Healthy volunteers were presented with animated triangles that moved in such a way that viewers would attribute mental states to them. In the sample frame shown, the larger triangle was seen as encouraging the smaller triangle to leave the enclosure. They were also presented with animated triangles that moved in a

more or less random fashion and thus would not elicit mentalizing. The highlighted areas show differences in the positron emission tomography (PET) scans of brain activation when these two viewing conditions were compared. (Reproduced, with permission, from Castelli et al. 2002.)

Figure 64–5 Individuals with autistic disorder often do not look into the eyes of others. Patterns of eye movements in individuals with autism were studied while the subjects watched clips from the film "Who's Afraid of Virginia Wolf?" When looking at human faces the subjects tended to look at the mouth rather than the eyes, and in scenes of intense interaction between people they tended to look at irrelevant places rather than at the faces of the actors. (Reproduced, with permission, from Klin et al. 2002.)

Typically developing viewer
Viewer with autism

The frequency of superior rote memory for facts related to special interests is higher still. Approximately onethird of individuals with autism have perfect pitch, even when not musically trained. It is unknown what networks in the brain give rise to these phenomena.

One explanation for islets of ability is that information processing is preferentially geared to tiny details at the cost of seeing the bigger picture (the "weak central coherence" account). A similar idea is that brain regions involved in perception are over-functioning (the "enhanced perceptual functioning" account), and another idea is that there is a preference for processing details that suit "systemizing" such as calendar knowledge. Neuropsychological data support both explanations, but decisive experiments still remain to be done. The drawing by the gifted artist with high-functioning autism in Figure 64–6 shows beautifully detailed city-scapes, as well as detailed numerical patterns and dates.

Some Neurodevelopmental Disorders Have a Known Genetic Basis

It is generally accepted that 10% to 15% of individuals with autism have other known genetic diseases. Many of these diseases are developmental disorders leading to other phenotypes of intellectual or learning disability, which may overlap with autism.

Intellectual disability is generally defined as measurable intelligence substantially below the population mean that is associated with significant limitations in adaptive functioning before the age of 18 years. Adaptive functioning is defined as how well one copes, at a given age, with common demands of life and includes such things as communication, social and interpersonal skills, and self-care.

Intelligence is usually defined by the intelligence quotient (or IQ), as determined by a variety of

Figure 64–6 Strikingly beautiful art work by George Widener. He is a highly accomplished and much admired outsider artist. In the attention to detail this drawing resembles the drawings of other autistic savant artists. The intricate topographical detail of a symmetrically arranged city, with rivers, bridges and tall buildings, is combined with minutely executed and seemingly abstruse calendar sequences. Mastery of the

calendar, and the ability to name the day of the week for any given date has often been described for autistic savants. The viewer of this drawing can partake in an otherwise very private world of space and time, numbers, and patterns. (Reproduced, with permission, from the Henry Boxer Gallery, London. www. outsiderart.co.uk.)

standardized tests, such as the Stanford-Binet or Wechsler Scales. These tests, in the general population, produce a range of scores that define a bell curve with the mean at 100 points. By definition an IQ below 2 standard deviations (below 70 points) is considered in the range of intellectual disability. Besides an IQ below 70, a person with intellectual disability also shows deficits in adaptive functioning. Like IQ, adaptive functioning is measured by standardized tests.

Fragile X Syndrome

Fragile X syndrome is a common form of chromosome X-linked intellectual disability. Patients show many similarities to autism, such as poor eye contact, a dislike of being touched, and repetitive behaviors. Its prevalence is approximately one in 4,000 boys and one in 8,000 girls. Estimates of the concurrence of autism and fragile X syndrome vary widely. In some early studies up to 25% of boys with autism were incorrectly diagnosed as having the fragile X syndrome. With the discovery of the gene for fragile X, diagnostic tests based on the genetic abnormality became available, lowering the percentage to approximately 3%. However, among children with fragile X syndrome, nearly 30% meet standard diagnostic criteria for autism.

The fragile X mutation is quite remarkable. The *FMR1* gene on the X chromosome includes the nucleotide triplet CGG. In normal individuals this triplet is repeated in approximately 30 copies. In fragile X syndrome patients the number of repeats is more than 200, with approximately 800 repeats being most common. As we have seen in Chapters 3 and 43, this expansion of trinucleotide repeats has since been recognized in other genes leading to neurological diseases, such as Huntington disease. When the number of CGG repeats exceeds 200, the *FMR1* gene becomes heavily methylated, and gene expression is shut off. Consequently, the fragile X mental retardation protein (FMRP) is lacking.

Lack of functional FMRP is considered responsible for fragile X syndrome. FMRP is a selective RNA-binding protein that renders messenger RNA dormant by blocking translation until protein synthesis is required. It is found at the base of dendritic spines together with ribosomes, where it regulates local dendritic protein synthesis that is needed both for synaptogenesis and for certain forms of long-lasting synaptic changes associated with learning and memory (see Chapters 66 and 67). Interestingly, a form of long-lasting synaptic change that requires local protein synthesis, the long-term depression of excitatory synaptic transmission, is actually enhanced in a mouse model of fragile X syndrome in

which the gene encoding FMRP has been deleted. Loss of FMRP may enhance long-term depression by allowing excess translation of messenger RNAs (mRNAs) important for synaptic plasticity.

Indeed, mice lacking FMRP do not require new protein synthesis for the induction of long-term synaptic depression. An exciting implication of these data is that chemical antagonists of the type 5 metabotropic glutamate receptor, mGluR5, activation of which is required for this form of long-term depression, may lessen the excess protein translation and thus perhaps have a therapeutic benefit.

Rett Syndrome

Another single-gene disorder sometimes confused with autism is Rett syndrome, a devastating disorder that affects girls primarily. Affected children appear normal from birth until 6 to 18 months of age, when they regress, losing speech and hand skills that they had acquired. Rett syndrome is progressive, and initial symptoms are followed by repetitive hand movements, a loss of motor control, and intellectual retardation. Girls with Rett syndrome can live into adulthood but never regain speech or the ability to use their hands. Its prevalence is approximately one in 15,000 girls.

Rett syndrome is an X-linked inherited disease caused by mutations in the *MeCP2* gene, which normally encodes a transcription factor that binds to methylated cytosine bases in DNA, thus regulating gene expression and chromatin remodeling. Although loss of *MeCP2* alters expression of a wide range of genes, an important contributing factor to the Rett syndrome phenotype may be the result of the reduced expression of the gene that codes for brain-derived neurotropic factor (BDNF). In mice reduced expression of this secreted neurotrophic factor leads to a phenotype much like the mouse model of Rett syndrome; overexpression of BDNF can substantially improve the phenotype in *MeCP2* mutant mice.

One might think that such a global abnormality in gene expression would lead to an even more severe phenotype than that of Rett syndrome. It turns out that one copy of *MeCP2* is essential for survival. Boys who have a single X chromosome and thus a single copy of *MeCP2* die prenatally or soon after birth of encephalopathy if they carry a mutant form of *MeCP2*. Although girls carry two X chromosomes, only one is active in any given cell. Because the choice of which X chromosome is active is random, girls with a *MeCP2* mutation on one X chromosome are mosaics: Some of their cells express the normal protein whereas others express the abnormal form. The cells with the normal protein

compensate and thus the phenotype develops into the Rett syndrome rather than the early lethal disease.

Down Syndrome

Down syndrome is the most common cause of birth defects in the United States and a major cause of intellectual disability. Each year approximately 100,000 infants worldwide are born with Down syndrome—approximately one in 1,000 births. Approximately 7% of children with Down syndrome also have autism.

Besides manifesting a characteristic set of facial and physical features, hypotonia, and congenital heart defects, Down syndrome is associated with cognitive defects and with early-onset Alzheimer disease. Among the cognitive deficits are poor spatial memory and difficulties in converting short-term to long-term memory. These memory defects are consistent with the fact that in individuals with Down syndrome the hippocampus is smaller than in typical development. The deficits are also the opposite of the exceptional short-term and long-term memory of many individuals with autism.

What are the specific genes that contribute to the cognitive symptoms of Down syndrome? Down syndrome results from the presence of an extra copy of chromosome 21 (trisomy of chromosome 21). Approximately 88% of these extra chromosomes are maternal in origin, 9% are paternal, and 3% occur at mitosis after fertilization. Studies of rare cases of partial trisomy of chromosome 21 suggest that the entire extra copy of the chromosome does not need to be expressed to have the full-blown syndrome.

A considerable part of the Down syndrome phenotype results from duplication of a 2-Mb region at segment 21q22.2 that contains 50 to 70 genes called *the critical Down region*. Examination of 27 transcripts that cover 80% of this region reveals several genes of potential interest for the cognitive deficit. These include a gene for two inwardly rectifying K⁺ channels (*KCNJ6*, Homo sapiens potassium inwardly rectifying channel, subfamily J, member 6, also know as Kir3.2 or GIRK2) that are expressed in the developing and adult central nervous system, the gene for a kainate-type glutamate receptor mGluR5 (*GRM5*) which regulates a form of plasticity implicated in fragile X syndrome, the single-minded gene 2 (*SIM2*), and the gene for a dual-functioning protein kinase called *minibrain kinase* (*Mnbk*).

Prader-Willi and Angelman Syndrome and Other Disorders

Few errors that involve an entire chromosome are compatible with life. Among the autosomes, in addition

to Down syndrome, only trisomy 18 and trisomy 13, each leading to severe intellectual disability, occur in an appreciable frequency, with a prevalence of one in 3,000 and one in 20,000 live births, respectively. Various numerical errors of the sex chromosomes occur but usually do not cause a significant degree of delay in cognitive development.

The only exception is Turner syndrome, which occurs in females missing an X chromosome. Girls who carry only the maternal X chromosome display a much higher prevalence of social-interaction difficulties similar to autism than do girls who carry the paternal X chromosome. This suggests genetic imprinting, where maternal and paternal copies of a gene are differentially expressed.

With imprinted genes, which represent only a small fraction (< 1%) of the genome, only one copy of the gene is expressed. In contrast, both the paternal and maternal alleles of nonimprinted genes are expressed. With paternally imprinted genes only the maternal allele is expressed. With maternally imprinted genes the opposite is true; only the paternally inherited allele is active. For example, with a maternally imprinted gene, either of the father's two alleles can be expressed in his children whereas the mother's alleles are silent. However, imprinting is reversible and is erased in the germ cells. Thus the same maternal alleles that are silenced in a mother's offspring can be active when they are transmitted by her son to his children.

Prader-Willi syndrome and Angelman syndrome, two related disorders with intellectual disability and possible connections with autism, are classic examples of imprinting. These two syndromes are usually caused by a specific deletion of the same region of chromosome 15 (Figure 64–7). However, individuals with Prader-Willi syndrome inherit the defective chromosome 15 from their father, whereas individuals with Angelman syndrome inherit the defective gene from their mother (see Chapter 3). Despite involving the same genetic mutation, the two syndromes have different symptoms. Prader-Willi syndrome is associated with mild intellectual disability, hypogonadism, and a hypothalamic abnormality that results in the inability to feel satiated from hunger, leading to morbid obesity. In contrast, Angelman syndrome is characterized by profound intellectual disability and an inappropriately happy demeanor with frequent laughing and smiling.

How can the same genetic deletion produce such different behavioral and physical changes? The answer lies in the differential patterns of imprinting of the paternal and maternal alleles of certain genes in this region of chromosome 15. If the paternal chromosome contains the deletion, as occurs in Prader-Willi syndrome, only

the maternal alleles are present. Thus any maternal alleles that are normally turned off because of imprinting will not be expressed in the offspring. Similarly, if the maternal chromosome contains the deletion, as occurs in Angelman syndrome, those genes that are normally turned off because of paternal imprinting will not be expressed in the offspring. Because different sets of genes are imprinted in males and females, individuals with Prader-Willi syndrome and Angelman syndrome have defects in expression of distinct sets of genes. Therefore, despite having similar deletions of chromosome 15, individuals with Prader-Willi and Angelman syndromes have completely different phenotypes.

Although Prader-Willi syndrome likely involves the loss of more than one imprinted gene on chromosome 15, the cause of Angelman syndrome has been narrowed to a single gene encoding the E3 ubiquitin ligase enzyme. Imprinted genes on chromosome 15 may also predispose for autism, as linkage studies have shown some positive signal from the proximal long

arm of chromosome 15. Indeed, a significant number of individuals with autism, perhaps as many as 1%, have maternal duplications of a portion of proximal chromosome 15 immediately adjacent to the Prader-Willi/Angelman syndrome region.

Other chromosome deletions that produce cognitive changes do not involve imprinted genes. Such deletions simply reduce the normal level of that gene's protein product by approximately 50%, because of the loss of one of the two alleles. Half the normal amount of some proteins is insufficient to support normal cellular function (known as *haploinsufficiency*), resulting in a particular behavioral phenotype. Most often these deletions involve varying degrees of intellectual disability and sometimes produce striking neuropsychiatric phenotypes.

One such example is Smith-Magenis syndrome, which results from the deletion of a single band on the short arm of chromosome 17. The syndrome is characterized by mild to moderate intellectual disability and

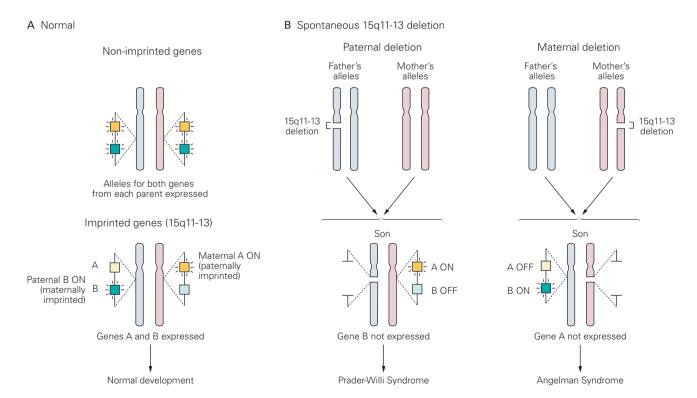

Figure 64–7 Imprinting in Prader-Willi and Angelman syndrome. Approximately 70% of Prader-Willi and Angelman syndrome patients inherit chromosome 15 from one parent with spontaneous (noninherited) deletions of the q11–13 interval. This interval contains imprinted genes with alleles that are either expressed or not depending on whether the chromosome was inherited from the father or mother. If the chromosome with the deletion is from the father, Prader-Willi

syndrome occurs because maternally imprinted genes on the corresponding interval of the intact maternal chromosome (gene B, for example) are not expressed. If the chromosome with the deletion is from the mother, the gene for ubiquitin ligase (*UBE3A*) will not be expressed in offspring because of its normal inactivation on the paternal chromosome caused by imprinting; loss of expression of this gene leads to Angelman syndrome.

marked hypersomnolence. Smith-Magenis syndrome patients engage in a variety of unusual self-mutilations that they seem unable to resist, such as onychotillomania (self-mutilation of the finger and toe nails) and polyembolokoilomania (insertion of foreign objects into body orifices). They also repeat two stereotypic behaviors, spasmodically squeezing their upper body ("self hug") and hand licking and page flipping ("lick and flip"). What is most remarkable is that although most patients with Smith-Magenis syndrome have a 4-Mb deletion, four patients have been identified recently with a mutation in only one of the genes in this interval, RAI1, which is expressed in neurons. Once the function of RAI1 becomes understood, it will be fascinating to consider how haploinsufficiency leads to the bizarre behaviors of Smith-Magenis syndrome.

Williams syndrome is also a segmental deletion but on the long arm of chromosome 7. Although no specific gene of the 25 to 30 genes within the deletion is singly responsible, the phenotype is nevertheless intriguing. Williams syndrome patients show specific dissociations of cognitive function, such as severe deficits in construction of visuospatial relations, yet have good language capabilities and do well in face recognition tests. However, the cognitive processes underlying these achievements differ from those used by typically developing children. Interestingly, Williams syndrome patients, regardless of family background and ethnicity, share somewhat similar personality traits marked by empathy and overfriendliness, making this syndrome in many ways the opposite of the stereotype of autism.

Probably hundreds of genes can lead to intellectual disability when mutated. Many of them encode proteins whose roles are central to brain development and function. For example, a form of lissencephaly ("smooth brain"), the loss of convolutions and gyri in the cerebral cortex, results from the mutation or deletion of the gene LIS1, which encodes a protein that normally participates in the regulation of cytoplasmic dynein heavy chains, which are essential for axonal transport (see Chapters 4 and 53). Intellectual disability also results from mutations of at least three genes with products that interact with Rho GTPases, leading to disruptions in signaling from the cell surface to the actin cytoskeleton that presumably alter neurite outgrowth. Mutations in Rab GTPases, which participate in vesicle fusion, also can lead to severe intellectual disability.

Other gene defects have much more subtle impacts on the nervous system and behavior. For example, Tony Monaco and co-workers studied an extended family, KE, in which a severe speech and language disorder is transmitted as an autosomal dominant condition because of a mutation in the gene *FOXP2*, which codes for a transcription factor. The *FOXP2* mutation causes faulty selection and sequencing of fine orofacial movements necessary for articulation, resulting in deficiencies in language processing and grammatical skills. *FOXP2* mutations have also been found in unrelated individuals with similar language deficits. Interestingly, nucleotide substitution rates in the *FOXP2* gene between species, a measure of evolutionary change, are accelerated in primates, suggesting that this gene had been a target of natural selection, possibly playing a significant role in the evolution of language in humans.

An Overall View

The study of neurodevelopmental disorders via cognitive neuroscience clearly illustrates the power of the synthesis of cognitive psychology and neuroscience and in fact moves this convergence into new directions. In the study of autism, for example, the mind blindness hypothesis has shown how cognitive theory can direct the search for the neural basis of a developmental disorder and how biological studies can open up a new window: the biology of social interactions.

A full understanding of the neurobiological basis of the many neurodevelopmental disorders that lead to intellectual disability will require the convergence of neuroscience, other medical disciplines, and functional genomics. A bottom-up approach—progressing from the identification of genes responsible for cognitive or behavioral disorders to an understanding of their effects on brain development—will clearly be crucial. At the same time, a top-down approach is needed, identifying the specific cognitive profile of each disorder and defining the critical neural circuits involved, using tools such as functional and structural brain imaging.

Autism is an example of a genetically complex disorder with a wide spectrum of manifestations, and the large differences between individual cases are often commented upon. Nevertheless, cognitive neuroscience has made advances in the difficult task of phenotyping patients and has helped pinpoint relevant brain regions and abnormal connections between them. This knowledge should be helpful in identifying the genetic and environmental risk factors that predispose to autism. Other developmental disorders that involve learning disabilities, especially those with much clearer patterns of inheritance than autism, are better suited to a bottom-up approach that begins with gene identification. Regardless of the approach,

the underlying mechanisms that lead to cognitive and behavioral impairment in humans are most likely to be uncovered by research that combines cognitive psychology, neuroscience, and molecular genetics.

Learning and Memory

Short-Term and Long-Term Memory Involve Different Neural Systems

Short-Term Memory Maintains Transient Representations of Information Relevant to Immediate Goals

Short-Term Memory Is Selectively Transferred to Long-Term Memory

Long-Term Memory Can Be Classified As Explicit or Implicit Explicit Memory Has Episodic and Semantic Forms

Explicit Memory Processing Involves at Least Four Distinct Operations

Episodic Knowledge Depends on Interaction Between the Medial Temporal Lobe and Association Cortices

Semantic Knowledge Is Stored in Distinct Association Cortices and Retrieval Depends on the Prefrontal Cortex

Implicit Memory Supports Perceptual Priming

Implicit Memory Can Be Associative or Nonassociative

Classical Conditioning Involves Associating Two Stimuli

Operant Conditioning Involves Associating a Specific Behavior with a Reinforcing Event

Associative Learning Is Constrained by the Biology of the Organism

Errors and Imperfections in Memory Shed Light on Normal Memory Processes

An Overall View

IN HIS MASTERFUL NOVEL One Hundred Years of Solitude Gabriel Garcia Marquez describes a strange plague that invades a tiny village and robs people of their memories. The villagers first lose personal

recollections, then the names and functions of common objects. To combat the plague, one man places written labels on every object in his home. But he soon realizes the futility of this strategy, because the plague eventually destroys even his knowledge of words and letters

This fictional incident reminds us of how important learning and memory are in everyday life. Learning refers to a change in behavior that results from acquiring knowledge about the world, and memory is the process by which that knowledge is encoded, stored, and later retrieved. Marquez's story challenges us to imagine life without the ability to learn and remember. We would forget people and places we once knew, and no longer be able to use and understand language or execute motor skills we had once learned; we would not recall the happiest or saddest moments of our lives, and would even lose our sense of personal identity. Learning and memory are essential to the full functioning and independent survival of people and animals.

In 1861 Pierre Paul Broca discovered that damage to the posterior portion of the left frontal lobe (Broca's area) produces a specific deficit in language. Soon thereafter it became clear that other mental functions, such as perception and voluntary movement, are also mediated by discrete parts of the brain (see Chapter 1). This naturally led to the question: Are there discrete neural systems concerned with memory? If so, is there a "memory center" or is memory processing widely distributed throughout the brain?

Contrary to the prevalent view that cognitive functions are localized in the brain, many students of learning doubted that memory is localized. In fact, until the middle of the 20th century many psychologists doubted that memory is a discrete function, independent of perception, language, or movement. One reason for the persistent doubt is that memory storage involves many different parts of the brain. We now appreciate, however, that these regions are not all equally important. There are several fundamentally different types of memory, and certain regions of the brain are much more important for some types of storage than for others.

During the past several decades researchers have made significant progress in the analysis and understanding of learning and memory. In this chapter we focus on three insights. First, there are several forms of learning and memory, each with its distinctive cognitive properties and mediated by specific brain systems. Second, memory can be deconstructed into discrete encoding, storage consolidation, and retrieval processes. Finally, imperfections and errors in remembering can provide clues about the nature and function of learning and memory.

Memory can be classified along two dimensions: (1) the time course of storage and (2) the nature of the information stored. We shall first consider the time course.

Short-Term and Long-Term Memory Involve Different Neural Systems

Short-Term Memory Maintains Transient Representations of Information Relevant to Immediate Goals

When we reflect on the nature of memory we usually think of the long-term memory that William James referred to as "memory proper" or "secondary memory." That is, we think of memory as "the knowledge of a former state of mind after it has already once dropped from consciousness." This knowledge depends on the formation of a memory trace that is durable, in which the representation persists even when its content has been out of conscious awareness for a long period.

Not all forms of memory, however, constitute "former states of mind." In fact, the ability to store information depends on short-term memory, called working memory, which maintains current, albeit transient, representations of goal-relevant knowledge. In humans working memory consists of at least two subsystems—one for verbal information and another for visuospatial information. The functioning of these two subsystems is coordinated by a third system called the *executive control processes*. Executive control

processes are thought to allocate attentional resources to the verbal and visuospatial subsystems, and to monitor, manipulate, and update stored representations.

We use the verbal subsystem when we attempt to keep speech-based (phonological) information in conscious awareness, as when we mentally rehearse a phone number just obtained from an operator. The verbal subsystem consists of two interactive components: a store that represents phonological knowledge and a rehearsal mechanism that keeps these representations active while we need them. Neuropsychological and neuroimaging data indicate that phonological storage depends on posterior parietal cortices, and rehearsal partially depends on articulatory processes in Broca's area.

The visuospatial subsystem of working memory retains mental images of visual objects and of the location of objects in space. The rehearsal of spatial and object information is thought to involve modulation of such representations in the parietal, inferior temporal, and extrastriate occipital cortices by the frontal and premotor cortices. Current research is concerned with whether visuospatial working memory might best be viewed as two subsystems, one for object knowledge and one for spatial knowledge.

Single-cell recordings in nonhuman primates indicate that some prefrontal neurons maintain spatial representations, others maintain object representations, and still others represent the integration of spatial and object knowledge. Although neurons concerned with working memory of objects tend to fall in the ventrolateral prefrontal cortex and those concerned with spatial knowledge tend to fall in the dorsolateral prefrontal cortex, all three classes of neurons are present in both prefrontal subregions (Figure 65–1).

Short-Term Memory Is Selectively Transferred to Long-Term Memory

In the mid-1950s startling new evidence about the neural basis of long-term memory emerged from the study of patients who had undergone bilateral removal of the hippocampus and neighboring regions in the medial temporal lobe as treatment for epilepsy. The first and best-studied case was a patient called H.M. studied by the psychologist Brenda Milner and the surgeon William Scoville. After H.M. died on December 2, 2008, his full name, Henry Molaison, was revealed to the world.

H.M., a 27-year-old man, had suffered for more than 10 years from untreatable temporal lobe epilepsy caused by brain damage sustained at age 7 years in a bicycle accident. As an adult his seizures rendered him unable to work or lead a normal life. At surgery Scoville removed the hippocampal formation, the

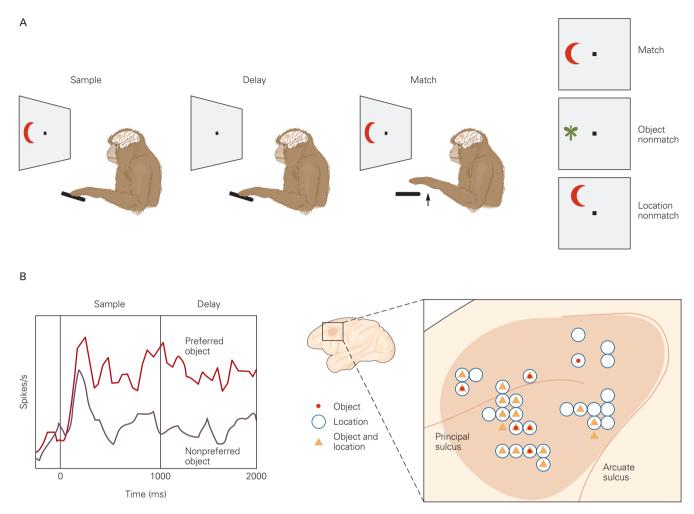

Figure 65–1 The prefrontal cortex maintains a working memory. (Adapted, with permission, from Rainer, Asaad, and Miller 1998.)

A. The role of prefrontal cortex in maintaining information in working memory is often assessed in monkeys using electrophysiological methods in conjunction with the delayed-match-to-sample (DMS) task. In this type of task each trial begins when the monkey grabs a response lever and fixates a small target at the center of a computer screen. An initial stimulus (the "sample") is briefly presented and must be held in working memory until the next stimulus (the "match") appears. In the task illustrated here the monkey was required to remember the sample ("what") and its location ("where") and release the lever only in response to stimuli that "matched" on both dimensions.

B. Neural firing rates in the primate lateral prefrontal cortex during the delay period in the task are often above baseline and represent responses to the type of stimulus (what), the location (where), and the integration of the two (what and where). At left is the activity of a prefrontal neuron to preferred objects (to which the neuron responds robustly) and to nonpreferred objects (to which the neuron responds minimally) during the task. Activity is robust when the monkey encounters the preferred object (sample) and during the delay. In the sketch at right the symbols represent recording sites where neurons that maintained each type of information (what, where, and what and where) were found. Typically, several types of neurons were found at one site; hence many symbols overlap and some symbols indicate more than one neuron.

amygdala, and parts of the multimodal association area of the temporal cortex bilaterally (Figure 65–2). After the surgery H.M.'s seizures were better controlled, but he was left with a devastating memory deficit (or amnesia). What was so remarkable about H.M.'s deficit was its specificity.

He still had normal working memory, for seconds or minutes, indicating that the medial temporal lobe is not necessary for transient memory. He also had long-term memory for events that had occurred before the operation. He remembered his name, the job he had held, and childhood events, although his memory of

B. The areas of temporal lobe resected (gray shading) in the patient known as H.M., viewed from the ventral surface of the brain (left hemisphere is on the right side of the image). Surgery was a bilateral, single-stage procedure, but to illustrate the structures that were removed the right side of the image is shown here intact. The longitudinal extent of the lesion is shown in a ventral view of the brain (top). Cross sections 1 through 3 show the estimated extent of areas of the brain

removed from H.M. (Adapted, with permission, from Corkin et al. 1997.)

C. Magnetic resonance image (MRI) scan of a parasagittal section from the left side of H.M.'s brain. The calibration bar at the right of the panel has 1-cm increments. The **asterisk** indicates the resected portion of the anterior temporal lobes. The **arrowhead** points to the remaining portion of the intraventricular portion of the hippocampal formation. Approximately 2 cm of preserved hippocampal formation is visible bilaterally. Note also the substantial degeneration in the enlarged folial spaces of the cerebellum. (Adapted, with permission, from Corkin et al. 1997.)

information acquired in the years just before surgery was not robust. In addition, he retained a command of language, including his vocabulary, indicating that semantic memory was preserved. His IQ remained unchanged in the range of bright–normal.

What H.M. now lacked, and lacked dramatically, was the ability to transfer new information from working memory into long-term memory. He was unable to retain for lengthy periods information about people, places, or objects that he had just encountered. Asked to remember a new telephone number, H.M. could repeat it immediately for seconds to minutes because of his intact working memory. But when distracted, even briefly, he forgot the number. H.M. could not recognize people he met after surgery, even when he met them again and again. For several years he saw Milner every month, yet each time she entered the room he reacted as though he had never seen her before. H.M. is not unique. All patients with extensive bilateral lesions of the limbic association areas of the medial temporal lobe from either surgery or disease show similar longterm memory deficits.

H.M. is a historic case because his deficit provided the first clear link between memory and the medial temporal lobe, including the hippocampus. Given the large size of the hippocampus proper, the question next arose: How extensive does a bilateral lesion have to be to produce a memory deficit? Clinical evidence from several patients as well as data from experimental animals suggests that a lesion restricted to any of the major components of the system can have a significant effect on long-term memory. For example Larry Squire, David Amaral, and their colleagues found that the patient R.B. had only one detectable lesion after a cardiac arrest—destruction of the pyramidal cells in the CA1 region of the hippocampus. Nevertheless, R.B.'s memory deficits were qualitatively similar to those of H.M., although quantitatively much milder.

The different subregions of the medial temporal lobe, which together comprise the medial temporal lobe memory system, may not have equivalent roles, however. For example, some areas in the medial temporal lobe circuit may be particularly important for object recognition. Damage to the perirhinal cortex that spares the underlying hippocampus produces a greater deficit in object recognition than do selective lesions of the hippocampus that spare the overlying cortex.

In contrast, some theorists have argued that the hippocampus may be relatively more important for spatial representation than for object recognition. In mice and rats lesions of the hippocampus interfere with memory for space and context, and single neurons in the hippocampus encode specific spatial

information (see Chapter 67). Functional imaging of the brain in healthy humans shows that activity increases in the right hippocampus when spatial information is recalled, and in the left hippocampus when words, objects, or people are recalled. These physiological findings are consistent with the clinical observation that lesions of the right hippocampus give rise to problems with spatial orientation whereas lesions of the left hippocampus cause defects in verbal memory.

Long-Term Memory Can Be Classified As Explicit or Implicit

Another crucial finding about H.M. was that not all types of long-term memory were impaired. Even though H.M. and other patients with damage to the medial temporal lobe had profound memory deficits, they were able to form and retain certain types of durable memories as well as healthy subjects.

For example, H.M. learned to draw the outlines of a star while looking at the star and his hand in a mirror (Figure 65–3). Like healthy subjects learning to remap hand-eye coordination, H.M. initially made many mistakes, but after several days of training his performance was error-free and comparable to that of healthy subjects. Nevertheless, he did not consciously remember having performed the task.

Later work by Squire and others made it clear that the long-term memory capabilities of H.M. and other amnesic patients are not limited to motor skills. These patients retain simple reflexive learning, including habituation, sensitization, classical conditioning, and operant conditioning (to be discussed later in this chapter). Furthermore, they are able to improve their performance on certain perceptual and conceptual tasks. For example, they do well with a form of memory called priming, in which perception of a word or object is improved by prior exposure. Thus, when shown only the first few letters of previously studied words, a subject with amnesia is able to generate the same number of words as normal subjects, even though the amnesic patient has no conscious memory of having recently studied the words (Figure 65–4).

Is this distinction between forms of long-term memory in amnesic patients a fundamental difference in normal memory function? To address this question the cognitive psychologists Peter Graf and Daniel Schacter examined healthy subjects and found two types of long-term memory that differed in whether conscious awareness was required for the recall.

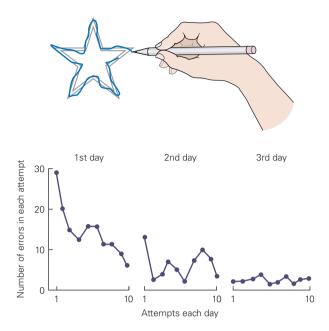

Figure 65–3 The amnesic patient H.M. could learn skilled movements. He was taught to trace between two outlines of a star while viewing his hand in a mirror. The graph plots the number of times, during each attempt, that he strayed outside the outlines as he drew the star. As with healthy subjects, H.M. improved considerably with repeated attempts despite the fact that he had no recollection of having performed the task before. (Reproduced, with permission, from Blakemore 1977.)

One type is an unconscious form of memory that is evident in the performance of a task and is known as *implicit memory* (also referred to as nondeclarative or procedural memory). Implicit memory is typically manifested in an automatic manner, with little conscious processing on the part of the subject. Different forms give rise to priming, skill learning, habit memory, and conditioning (Figure 65–5).

The other type is the deliberate or conscious retrieval of previous experiences as well as conscious recall of factual knowledge about people, places, and things. This type is known as *explicit memory* (or declarative memory). Explicit memory is highly flexible; multiple pieces of information can be associated under different circumstances. Implicit memory, however, is tightly connected to the original conditions under which the learning occurred.

Explicit Memory Has Episodic and Semantic Forms

The Canadian psychologist Endel Tulving first developed the idea that explicit memory can be further

classified into episodic memory (the memory of personal experiences or autobiographical memory) and semantic memory (memory for facts). *Episodic memory* is used to recall that we saw the first flowers of spring yesterday or that we heard Beethoven's "Moonlight Sonata" several months ago. *Semantic memory* is used to learn the meanings of new words or concepts. The medial temporal lobe plays a critical role in both episodic and semantic memory, as is evident in patients like H.M., who have difficulties in forming and retaining new conscious memories of their personal experiences or the meanings of new concepts.

We have learned two additional important things about explicit memory. First, the brain does not have a single long-term store of explicit memories. Instead the storage of any item of knowledge is widely distributed among many brain regions and can be accessed independently (by visual, verbal, or other sensory clues).

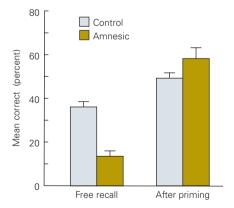

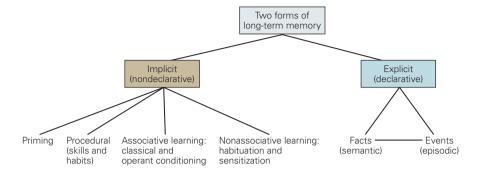

Figure 65–4 Amnesic and normal control subjects were tested on recall of words under two conditions. First they were presented with common words and then asked to recall the words (free recall). Amnesic patients did not do well on this test. However, when subjects were given the first three letters of a word and instructed simply to form the first word that came to mind (completion), the amnesic subjects performed as well as normal subjects. The baseline guessing rate in the word completion condition was 9%. (Reproduced, with permission, from Squire 1987.)

Second, explicit memory is mediated by at least four related but distinct types of processing: encoding, storage, consolidation, and retrieval.

Explicit Memory Processing Involves at Least Four Distinct Operations

Encoding is the process by which new information is attended and linked to existing information in memory. The extent of this process is critically important for determining how well the learned material will be remembered. For a memory to persist and be well remembered, the incoming information must be encoded thoroughly, what the psychologists Fergus Craik and Robert Lockhart called "deep" encoding. This is accomplished by attending to the information and associating it with knowledge that is already well established in memory. Memory encoding also is stronger when one is well motivated to remember.

Storage refers to the neural mechanisms and sites by which memory is retained over time. One of the remarkable features about long-term storage is that it seems to have an almost unlimited capacity; there is no known limit to the amount of information in long-term storage. In contrast, working memory storage is very limited; psychologists believe that human working memory can hold only a few pieces of information at any one time.

Consolidation is the process that makes the temporarily stored and still labile information more stable. As we shall learn in the next two chapters, consolidation involves expression of genes and protein synthesis that give rise to structural changes at synapses.

Finally, retrieval is the process by which stored information is recalled. It involves bringing back to mind different kinds of information that are stored in different sites. Retrieval of memory is much like perception; it is a constructive process and therefore subject to distortion much as perception is subject to illusions (Box 65–1).

Retrieval of information is most effective when a retrieval cue reminds individuals of how they initially encoded an experience. For example, in a classic behavioral experiment Craig Barclay and colleagues asked some subjects to encode sentences such as "The man lifted the piano." On a later test, "something heavy" was a more effective cue for recalling piano than "something with a nice sound." Other subjects, however, encoded the sentence "The man tuned the piano." For them, "something with a nice sound" was a more effective retrieval cue for piano than "something heavy." Retrieval, particularly of explicit memories, also is partially dependent on working memory.

Episodic Knowledge Depends on Interaction Between the Medial Temporal Lobe and Association Cortices

Although studies of amnesic patients during the past few decades have refined our understanding of various types of memory, medial temporal lobe damage affects all four operations of memory—encoding, storage, consolidation, and retrieval—and thus it is often difficult to discern how the medial temporal lobe contributes to each. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) allow us to scan the healthy brain in the process of building new memories or retrieving existing memories, and thus to identify specific regions that are active during different processes.

Functional MRI scans show that activity in the medial temporal lobe is greater when subjects engage in deep encoding (eg, attending to the meaning of information by judging whether a word is concrete or abstract) than when they engage in shallow encoding (eg, judging whether a word is presented in upper or lower case letters). Activity in parts of the left prefrontal cortex is also enhanced during deep encoding,

Box 65–1 The Transformation of Explicit Memories

How accurate is explicit memory? This question was explored by the psychologist Frederic Bartlett in a series of studies in the 1930s in which the subjects were asked to read stories and then retell them. The recalled stories were shorter and more coherent than the original stories, reflecting reconstruction and condensation of the original.

The subjects were unaware that they were editing the original stories and often felt more certain about the edited parts than about the unedited parts of the retold stories. They were not confabulating; they were merely interpreting the original material so that it made sense on recall.

Observations such as these lead us to believe that explicit memory, at least episodic (autobiographical) memory, is a constructive process like sensory perception. In fact, explicit memory is a product of the perceptual process. Sensory perception is not a passive recording of the external world but a process in which

sensory signals produce information that is shaped by the way in which afferent pathways process those signals.

It is also constructive in the sense that individuals perceive the environment from the standpoint of a specific point in space as well as a specific point in their own history. As described in Chapter 27, optical illusions nicely illustrate the active role of perceptual processes in arriving at our personal knowledge of our surroundings.

Likewise, once information is stored, recall is not an exact copy of the information stored. Past experiences are used in the present as cues that help the brain reconstruct a past event. During recall we use a variety of cognitive strategies, including comparison, inference, shrewd guessing, and supposition, to generate a memory that not only seems coherent to us but is also consistent with other memories and with our "memory of the memory."

suggesting that frontal lobe and medial temporal lobe processing contribute to encoding episodic memory.

Anthony Wagner and his colleagues tested the relation between frontal and medial temporal lobe activity during encoding of an experience and the later remembering of the experience. Subjects were scanned using event-related fMRI while they learned a long series of words (event-related fMRI allows researchers to examine brain activity based on participants' responses to specific items or events). Their memory of the words was then tested outside the scanner to compare their recall with the activity recorded while learning the series of words. At the time of encoding, activity in several regions of the left prefrontal cortex was enhanced when subjects were studying words that they were later able to recall (Figure 65-6). Using similar methods to examine the encoding of memories of pictures, James Brewer and John Gabrieli and their colleagues found greater activity in the right prefrontal cortex during encoding of pictures that were later recalled compared to pictures that could not be recalled.

Both studies also revealed greater activity in the medial temporal lobe during encoding of stimuli that were subsequently remembered compared to those that were forgotten. This is further evidence that episodic learning depends on interaction between cognitive control processes in the prefrontal cortex and associative binding mechanisms in the medial temporal lobe.

Interaction between the medial temporal lobe and distributed cortical regions is also central in current thinking about memory consolidation. Recall that patient H.M., whose medial temporal lobe was surgically removed, could still recall childhood memories. In fact, early observations suggested that H.M. could recall many of the experiences of his life up until several years before his operation. These observations of H.M. and other amnesic patients with damage to the medial temporal lobe suggest that old memories are not stored in the medial temporal lobe itself; if they were, H.M. would not be able to recall his early experiences. Rather, they are stored in various other cortical regions.

According to Larry Squire and others, the medial temporal region may play a temporary role in the consolidation of memories, but after a sufficiently long period is no longer needed as memories can be retrieved directly from cortical regions. This finding is consistent with the fact that amnesic patients are better able to recall remote memories than memories from the period just before they became amnesic.

As with studies of encoding, studies of retrieval of episodic knowledge have implicated the prefrontal cortex and medial temporal lobe. In one study, monkeys were trained to associate a specific visual object with a preceding visual cue. During training the monkeys learn that they will receive a reward if they press a lever when a specific object is shown, but only when that object is preceded by the learned visual cue. Electrophysiological recordings reveal that, after training, the visual cue activates neurons in the monkey's inferior temporal cortex during the recall of the stored visual memory.

Importantly, even after the monkey has undergone brain surgery to prevent the afferent flow of visual information from primary visual cortex to inferior temporal cortex, the visual cue is able to elicit the correct behavioral response and to elicit firing in the inferior temporal cortex neurons. This implies that information about the visual cue must reach neurons in the inferior temporal cortex through a "top-down" pathway in which signals from the primary visual cortex activate neurons in prefrontal cortex that in turn activate neurons in the inferior temporal cortex. When this "top-down" pathway is also surgically interrupted, the monkeys fail to respond to the visual cue, which can no longer trigger activity in the inferior temporal cortex neurons (Figure 65–7). PET and fMRI scans of human subjects asked to recall or recognize

previously studied words or pictures show activity in the anterior and lateral prefrontal cortex.

The retrieval of contextual or event details associated with episodic memory also involves activity in the medial temporal lobe, particularly in the hippocampus. Medial temporal lobe activity is thought to facilitate the activation of neocortical representations that were present during encoding. Consistent with this perspective, Yasushi Miyashita and colleagues have demonstrated that signals from the medial temporal lobe precede the recruitment of episodic knowledge in the neocortex. Mark Wheeler and colleagues and Lars Nyberg and colleagues observed similar patterns of activation in visual and auditory association areas during both the encoding and retrieval of pictures and sounds. As with encoding of episodic memory, retrieval involves a complex interaction between the medial temporal lobe and distributed cortical regions, including the prefrontal cortex and other high-level association areas.

Semantic Knowledge Is Stored in Distinct Association Cortices and Retrieval Depends on the Prefrontal Cortex

Semantic knowledge is our general knowledge about the world, encompassing facts, concepts, and information

Figure 65–6 Activity in the prefrontal cortex and medial temporal lobe during an experience is essential to remembering the experience.

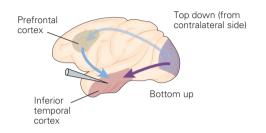

Neural activity during encoding of visual events (presentation of words) was measured using functional magnetic resonance imaging (fMRI). Subsequently, recall of the studied words was tested and each word was classified as either remembered or forgotten. The scans taken during encoding were then sorted into two groups: those made during encoding of words that were later remembered and those made during encoding of words that were later forgotten. This subsequent memory analysis reveals greater activation in regions of the left prefrontal cortex and medial temporal lobe during the encoding of words later remembered than those later forgotten (locations denoted by white arrows). At right are the observed fMRI responses in these regions for words later remembered (red line) and those later forgotten (dashed line). (Adapted from, with permission, from Wagner et al. 1998.)

about objects, as well as words and their meanings. Semantic knowledge is distinguished from episodic knowledge in that it is typically not associated with the context in which the information was acquired. It is stored in a distributed manner in the neocortex, including the lateral and ventral temporal lobes.

The organization and flexibility of semantic knowledge is remarkable. Consider the concept "elephant." When first learned through a picture it appears to be quite simple. With further learning, however, many images of elephants become associated with a name, at first spoken and then written. Later other pieces of information are associated: elephants are living things, they live in a particular environment and have unique patterns of behavior, they emit distinctive sounds and are often gray in color, and they perform in circuses. Given this associative structure—which would collectively correspond to the concept "elephant"—any one feature, such as the word *elephant*, can serve as a cue that leads to recovery of other associated features.

There is no single storage site for all of the semantic knowledge that we have acquired over our lifetime. Rather, the semantic components of a concept are distributed among many brain regions. Specific brain regions are dedicated to representing specific features (eg, form, color, or motion), such that a lesion in one

region can impair a specific type of knowledge associated with a particular concept while sparing others.

Rosaleen McCarthy and Elizabeth Warrington described patients whose knowledge about living things was impaired while their knowledge about inanimate objects was intact. For example, one patient correctly defined towel as "material used to dry people," but incorrectly defined wasp as a "bird that flies." Other patients demonstrate the reverse deficit. The brain appears to organize semantic knowledge according to conceptual primitives, eg, form and function. Because some categories are particularly dependent on information about form (eg, living things) whereas others depend on knowledge of function (eg, inanimate things), focal brain damage can result in the loss of memory for particular semantic categories while sparing knowledge of others.

Neuroimaging studies using PET and fMRI provide more evidence about how different categories of knowledge are represented in the intact human brain. When people name pictures of animals there is greater activity in left inferior temporal regions, which represent information about the form of objects, than when they name pictures of tools. In contrast, tool naming is associated with activity in left premotor regions, which represent information about the patterns of motor

Figure 65–7 (Opposite) The prefrontal cortex contributes to recall of associated knowledge. (Reproduced, with permission, from Tomita et al. 1999.)

A. The experimental design includes "bottom-up" and "topdown" retrieval conditions. A monkey was trained to associate a specific object with a prior visual cue. During testing the monkey was shown a visual cue on a screen. After a delay the monkey was then shown one of several objects (choice). The monkey had to choose whether the object is the one that is associated with the visual cue (by releasing a lever). The posterior corpus callosum of the monkeys in the study was partially split so that the bottom-up sensory signal from visual cortex could not directly reach visual areas in the opposite hemisphere. 1. In the bottom-up retrieval condition the retrieval cue and choice object are presented in the right visual hemifield contralateral to the recording site (electrode) in the left inferior temporal cortex. Because the left hemisphere processes the right visual field, visual information enters the primary visual cortex in the same hemisphere as the recording electrode. The monkey was able to choose the correct object associated with the cue (data not shown) indicating that bottom-up sensory signals are sufficient for retrieval. The bottom-up signal in response to the visual cue also elicits a large increase in neural firing rate in the inferior temporal cortex neurons. 2. In the topdown retrieval condition the cue is presented in the left visual hemifield ipsilateral to the recording site, whereas the choice object is presented contralaterally in the right visual hemifield.

Thus visual information about the cue enters the hemisphere opposite to the recording site. Because the posterior corpus callosum is cut, there is no direct bottom-up pathway from right visual cortex to left inferior temporal cortex. Nonetheless the visual cue is able to elicit a strong electrophysiological response in inferior temporal cortex neurons in the left hemisphere and the monkey is able to choose the correct object associated with the cue. In this condition visual information from the right hemisphere crosses over to the left hemisphere through the intact anterior portion of the corpus callosum. Top-down signals from prefrontal cortex, which carry information about the retrieval cue, elicit neuronal firing and retrieval of associated representations through feedback connections to the inferior temporal cortex.

B. When the corpus callosum is fully split, visual information from the contralateral hemisphere can no longer reach the ipsilateral prefrontal cortex. This prevents top-down retrieval signals from being transmitted to inferior temporal neurons. As a result, neurons in the left inferior temporal cortex are no longer activated by the presentation of the visual cue to the left hemifield. In addition, the monkeys no longer choose the correct object when the cue is presented to the contralateral visual hemifield. In contrast, left inferior temporal cortex neurons show a strong response when the cue is presented to the right visual hemifield because the bottom-up pathway from left visual cortex to left inferior temporal cortex is intact.

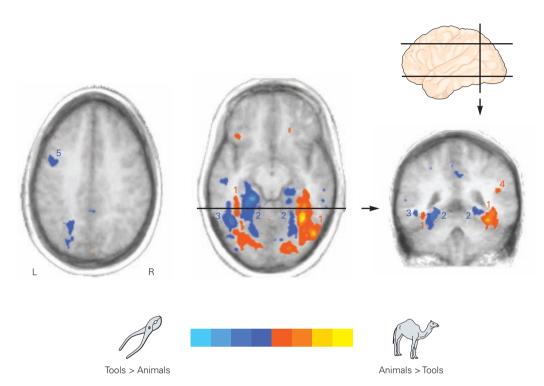

Figure 65–8 Neural correlates of category-specific knowledge. Functional magnetic resonance imaging (fMRI) data show neural activity associated with silent naming of animals and tools shown in pictures. Regions with greater activity when animals were named (shown in yellow and red) include the lateral fusiform gyrus (1) and right superior temporal sulcus (4).

Regions with greater activity when tools were named (blue) include the medial fusiform gyrus (2), left middle temporal gyrus/inferior temporal sulcus (3), and left ventral premotor cortex (5). (Reproduced, with permission, from Martin and Chao 2001.)

movements associated with the use of an object, and in left middle temporal regions, which represent information about how objects move in space (Figure 65–8).

Implicit Memory Supports Perceptual Priming

Implicit memory stores forms of knowledge that are typically acquired without conscious effort and which guide behavior unconsciously. Priming is a type of implicit memory that operates in amnesic patients as well as healthy subjects, suggesting that it does not depend on medial temporal lobe structures.

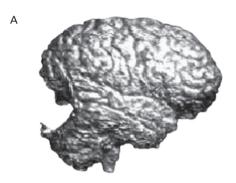

Two types of priming have been proposed. *Conceptual priming* provides easier access to task-relevant semantic knowledge because that knowledge has been used before. It is correlated with decreased activity in left prefrontal regions that subserve initial retrieval of semantic knowledge. In contrast, *perceptual priming* occurs within a specific sensory modality, and according to Tulving and Schacter it depends on cortical

modules that operate on sensory information about the form and structure of words and objects.

Damage to unimodal sensory regions of cortex impairs modality-specific perceptual priming. For example, one patient with an extensive lesion of the right occipital lobe failed to demonstrate visual priming for words but had normal explicit memory (Figure 65–9). This condition is the reverse of that found in amnesic patients such as H.M., and provides further evidence that the neural mechanisms of priming are distinct from those for explicit memory.

Visual priming is almost always correlated with decreased activity in higher-order visual (extrastriate) areas of cortex. Randy Buckner and his colleagues using fMRI found that activity in extrastriate cortex was greater during the initial exposure to an object than when the object was presented again later. These findings parallel the finding that activity in the left prefrontal cortex is reduced during conceptual priming. Most tasks include both perceptual and conceptual priming, and there probably are no sharp distinctions between the two.

Other forms of nondeclarative memory subserve the learning of habits, the learning of motor, perceptual, and cognitive skills, and the formation and expression of conditioned responses. In general, these forms of implicit memory are characterized by incremental learning, which proceeds gradually with repetition. The neural circuits that initiate habit, motor skill, and conditioned learning are independent of the medial temporal lobe system responsible for explicit memory.

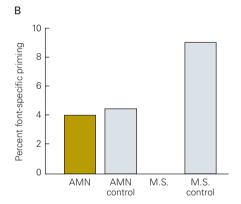

Figure 65–9 The right occipital cortex is required for visual priming for words. (Adapted with permission, from Vaidya et al. 1998.)

A. Structural magnetic resonance imaging (MRI) depicts the near complete removal of the right occipital cortex in a patient, M.S., who suffered pharmacologically intractable epilepsy with a right occipital cortical focus.

B. Font-specific priming is intact in amnesic patients (AMN) and their controls as well as in the controls for patient M.S., but not in M.S. himself. Font-specific priming is a form of visual priming in which the individual is better able to identify a briefly flashed word when the type font is identical to an earlier presentation, compared to identification when the font is different (priming equals performance when the font is the same minus performance when the font is different). The patient M.S. has normal explicit memory, even for visual cues (data not shown), but lacks implicit memory for specific properties of visually presented words.

For example, H.M. is able to acquire new visuomotor skills, like the mirror-tracing task (see Figure 65–3).

New perceptual, motor, or cognitive abilities are also learned through repetition. With practice, performance becomes more accurate and faster, and these improvements generalize to learning novel information. Skill learning moves from a cognitive stage, where knowledge is represented explicitly and the learner must pay a great deal of attention to performance, to an autonomous stage, where the skill can be executed without much conscious attention. As an example, driving a car initially requires that one pay attention to each component of the skill, but after practice one no longer attends to the individual components.

The learning of sensorimotor skills depends in part on the basal ganglia, cerebellum, and neocortex. Dysfunction of the basal ganglia in patients with Parkinson and Huntington disease impairs learning of motor skills. Patients with cerebellar lesions also have difficulties acquiring some motor skills, and functional imaging of healthy individuals during sensorimotor learning shows changes in the activity of the basal ganglia and cerebellum. Finally, skilled behavior can depend on structural changes in motor neocortex, as seen by the expansion of the cortical representation of the fingers in musicians (see Chapter 67).

Perceptual learning improves the ability to make sense of novel sensory inputs, as in learning to read mirror-reversed text or recognizing novel objects by reference to familiar categories. Amnesic patients with damage to the medial temporal lobe can learn to read mirror-reversed text but this learning is mildly impaired in Huntington disease and variably impaired in Parkinson disease. Patients with cerebellar lesions have no difficulty with perceptual learning, even though the learning of motor skills is impaired.

A neuroimaging study by Russell Poldrack and his colleagues suggests that extensive practice with mirror reading produces a shift in the parts of the brain involved in the task. In this study performance of the mirror-reading task before practice was correlated with activity in ventral visual processing regions as well as extensive activity in the parietal cortex. After practice, activity decreased in the parietal cortex but increased in the left inferior temporal cortex, a region associated with representing visual form (Figure 65-10). These results reflect a transition from having to mentally rotate the mirror-reversed words to the ability to read directly the reversed letters. Different neural processes are involved once skilled performance moves from the cognitive to the autonomous stage. Similar neural changes have been observed in imaging studies of motor and visual-motor skill learning.

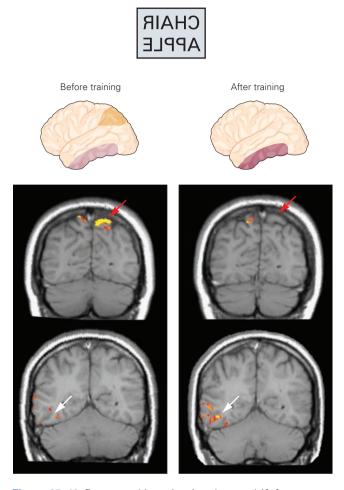

Figure 65–10 Perceptual learning involves a shift from cognitive to autonomous stages that use different neural pathways. Subjects are asked to read mirror-reversed text, something most people rarely encounter. Prior to training individuals rely on the parietal cortex (red arrow) and to a lesser extent the inferior temporal cortex (white arrow). After extensive training the processing pathways involved in the task appear to be different. Individuals rely less on the parietal cortex and more on the inferior temporal cortex. (Reproduced, with permission, from Poldrack et al. 1998.)

Implicit memory also underlies habit learning or Pavlovian associative conditioning, the gradual learning about the predictive relationship between a stimulus and a response (discussed later). Habit learning in humans has been studied using the probabilistic classification task, where subjects attempt to predict accurately one of two possible outcomes based on the presentation of a set of cues, with each cue having a probabilistic relation to each outcome. For example, subjects may be asked to predict the weather (rain or sunshine) based on a set of cue cards (Figure 65–11).

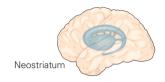

Because the associations between the cues and outcomes are probabilistic, thus requiring numerous trials to learn, explicit (conscious) memory of specific trials is not as useful for successful performance as the gradual accumulation of knowledge about the stimulus-outcome associations. Barbara Knowlton and colleagues have shown that, in contrast to patients with medial temporal lobe lesions, patients with basal ganglia disorders are severely impaired in this task.

Implicit Memory Can Be Associative or Nonassociative

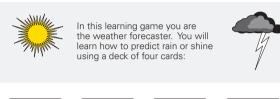

Our consideration of implicit memory has so far focused on humans. But some forms of implicit memory can also be studied in nonhuman animals, and animal studies have distinguished two types of implicit memory: nonassociative and associative. With nonassociative learning an animal learns about the properties of a single stimulus. With associative learning the animal learns about the relationship between two stimuli or between a stimulus and a behavior.

Nonassociative learning results when a subject is exposed once or repeatedly to a single type of stimulus. Two forms of nonassociative learning are common in everyday life: habituation and sensitization. Habituation, a decrease in a response, occurs when a benign stimulus is presented repeatedly. For example, most people in the United States are startled when they first hear the sound of a firecracker on Independence Day, but as the day progresses they become accustomed to the noise and do not respond. Sensitization (or pseudoconditioning) is an enhanced response to a wide variety of stimuli after the presentation of an intense or noxious stimulus. For example, an animal will respond more vigorously to a mild tactile stimulus after receiving a painful pinch. Moreover, a sensitizing stimulus can override the effects of habituation, a process called dishabituation. For example, after the startle response to a noise has been reduced by habituation, one can restore the intensity of response to the noise by delivering a strong pinch.

With sensitization and dishabituation the timing of stimuli is not important because no association between stimuli must be learned. In contrast, with two forms of associative learning the timing of the stimuli to be associated is critical. Classical conditioning involves learning a relationship between two stimuli, whereas operant conditioning involves learning a relationship between the organism's behavior and the consequences of that behavior.

A Prediction task

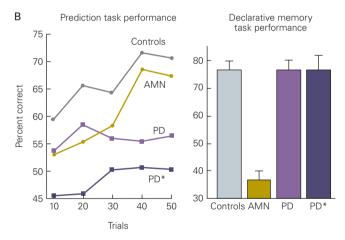

Figure 65–11 Learning predictive relationships involves the neostriatum.

A. Subjects are instructed to predict whether the weather will be rain or sunshine based on a set of cue cards. Each cue card has a probabilistic relation to each weather outcome (eg, predicting sunshine either 75, 57, 43, or 25% of the time). Subjects attempt to learn these relations during training and they are told after each trial whether their prediction is correct or incorrect.

B. Performance on the prediction task across the first 50 training trials is plotted on the left; performance results on a declarative memory test are shown on the right. Amnesic patients (AMN) initially learn the prediction task at the same rate as healthy control subjects, although their performance on the declarative memory task is impaired. By contrast, patients with Parkinson disease (PD), who suffer impairments in basal ganglia function, perform poorly on the prediction task but perform as well as controls on the declarative memory task. PD* identifies a subgroup of the Parkinsonian patients with the most severe symptoms. (Reproduced, with permission, from Knowlton, Mangels, and Squire 1996.)

Classical Conditioning Involves Associating Two Stimuli

Classical conditioning was first described at the turn of the century by the Russian physiologist Ivan Pavlov. The essence of classical conditioning is the pairing of two stimuli. The conditioned stimulus (CS), such as a light, a tone, or a touch, is chosen because it produces either no overt response or a weak response usually unrelated to the response that eventually will be learned. The reinforcement, or unconditioned stimulus (US), such as food or a shock, is chosen because it normally produces a strong and consistent response (the unconditioned response), such as salivation or withdrawal of the leg. Unconditioned responses are innate; they are produced without learning. Repeated presentation of a CS followed by a US gradually elicits a new or different response called the conditioned response.

One way of explaining conditioning is that repeated pairing of the CS and US causes the CS to become an anticipatory signal for the US. With sufficient experience an animal will respond to the CS as if it were anticipating the US. For example, if a light is followed repeatedly by the presentation of meat, eventually the sight of the light itself will make the animal salivate. Thus classical conditioning is the way an animal learns to predict events.

The probability of occurrence of a conditioned response decreases if the CS is repeatedly presented without the US. This process is known as extinction. If a light that has been paired with food is later repeatedly presented in the absence of food, it will gradually cease to evoke salivation. Extinction is an important adaptive mechanism; it would be maladaptive for an animal to continue to respond to cues that are no longer meaningful to it. The available evidence indicates that extinction is not the same as forgetting, but that something new is learned—the CS now signals that the US will not occur.

For many years psychologists thought that classical conditioning resulted as long as the CS preceded the US by a critical time interval. According to this view, each time a CS is followed by a US (reinforcing stimulus) a connection is strengthened between the internal representations of the stimulus and response or between the representations of one stimulus and another. The strength of the connection was thought to depend on the number of pairings of CS and US.

A substantial body of evidence now indicates that classical conditioning cannot be adequately explained simply by the fact that two events or stimuli occur one after the other (Figure 65–12). Indeed, it would not be

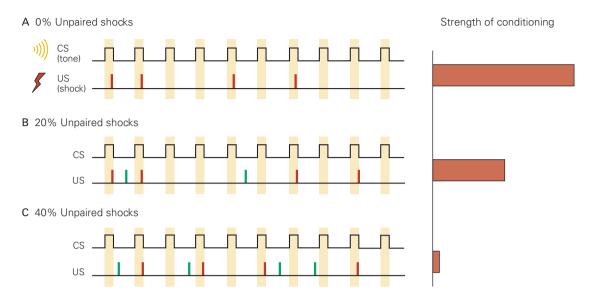

Figure 65–12 Classical conditioning depends on the degree to which two stimuli are correlated. In this experiment on rats a tone (the conditioned stimulus or CS) was paired with an electric shock (the unconditioned stimulus or US) in four out of 10 of the trials (red ticks). In some trial blocks the shock was presented without the tone (green ticks). The degree of conditioning was evaluated by determining how effective the tone alone was in suppressing lever-pressing to obtain food. Suppression of lever-pressing is a sign of a conditioned

defensive response, freezing. (Adapted, with permission, from Rescorla 1968.)

A. Maximal conditioning occurred when the US was presented only with the CS.

B–C. Little or no conditioning was evident when the shock occurred without the tone as often as with it (40%). Some conditioning occurred when the shock occurred 20% of the time without the tone.

adaptive to depend solely on sequence. Rather, all animals capable of associative conditioning, from snails to humans, remember actual relationships rather than simply sequential events. Thus classical conditioning, and perhaps all forms of associative learning, enables animals to distinguish events that reliably occur together from those that are only randomly associated.

Lesions in several regions of the brain affect classical conditioning. A well-studied example is conditioning of the protective eyeblink reflex in rabbits, a form of motor learning. A puff of air to the eye naturally causes an eyeblink. A conditioned eyeblink can be established by pairing the puff with a tone that precedes the puff. The conditioned response (an eyeblink in response to a tone) is abolished by a lesion at either of two sites. Damage to the vermis of the cerebellum abolishes the conditioned response but does not affect the unconditioned response (eyeblink in response to a puff of air). Interestingly, neurons in the same area of the cerebellum show learning-dependent increases in activity that closely parallel the development of the conditioned behavior. A lesion in the interpositus nucleus, a deep cerebellar nucleus, also abolishes the conditioned eyeblink. Thus both the vermis and the deep nuclei of the cerebellum play an important role in conditioning the eyeblink and perhaps other simple forms of classical conditioning involving skeletal muscle movement.

Operant Conditioning Involves Associating a Specific Behavior with a Reinforcing Event

A second major paradigm of associative learning, discovered by Edgar Thorndike and systematically studied by B. F. Skinner and others, is operant conditioning (also called trial-and-error learning). In a typical laboratory example of operant conditioning a hungry rat or pigeon is placed in a test chamber in which the animal is rewarded for a specific action. For example, the chamber may have a lever protruding from one wall.

Because of previous learning, or through play and random activity, the animal will occasionally press the lever. If the animal promptly receives a positive reinforcer (eg, food) after pressing the lever, it will begin to press the lever more often than the spontaneous rate. The animal can be described as having learned that among its many behaviors (for example, grooming, rearing, and walking) one behavior is followed by food. With this information the animal is likely to press whenever it is hungry.

If we think of classical conditioning as the formation of a predictive relationship between two stimuli (the CS and the US), operant conditioning can be considered as the formation of a predictive relationship between an action and an outcome. Unlike classical conditioning, which tests the responsiveness of a reflex to a stimulus, operant conditioning tests behavior that occurs either spontaneously or without an identifiable stimulus. Operant behaviors are said to be emitted rather than elicited. In general, actions that are rewarded tend to be repeated, whereas actions followed by aversive, although not necessarily painful, consequences tend not to be repeated. Many experimental psychologists feel that this simple idea, called the law of effect, governs much voluntary behavior.

Because operant and classical conditioning involve different kinds of association—an association between an action and a reward or between two stimuli, respectively—one might suppose the two forms of learning are mediated by different neural mechanisms. However, because the laws of operant and classical conditioning are quite similar, the two forms of learning may use the same neural mechanisms. For example, timing is critical in both. In operant conditioning the reinforcer usually must closely follow the operant action. If the reinforcer is delayed too long, only weak conditioning occurs. Similarly, classical conditioning is generally poor if the interval between the conditioned and unconditioned stimuli is too long or if the unconditioned stimulus precedes the conditioned stimulus.

Associative Learning Is Constrained by the Biology of the Organism

Animals generally learn to associate stimuli that are relevant to their survival. For example, animals readily learn to avoid certain foods that have been followed by a negative reinforcement (eg, nausea produced by a poison), a phenomenon termed *taste aversion*.

Unlike most other forms of conditioning, taste aversion develops even when the unconditioned response (poison-induced nausea) occurs after a long delay, up to hours after the CS (specific taste). This makes biological sense, because the ill effects of infected foods and naturally occurring toxins usually follow ingestion only after some delay. For most species, including humans, taste-aversion conditioning occurs only when certain tastes are associated with illness. Taste aversion develops poorly if a taste is followed by a painful stimulus that does not produce nausea. Animals do not develop an aversion to a visual or auditory stimulus that has been paired with nausea.

Errors and Imperfections in Memory Shed Light on Normal Memory Processes

Memory allows us to revisit our personal past, provides access to a vast network of facts, associations, and concepts, and supports learning. But memory is not perfect. We often forget events rapidly or gradually, sometimes distort the past, and occasionally remember events that we would prefer to forget. In the 1930s the British psychologist Frederic Bartlett reported experiments in which people read and tried to remember complex stories. He showed that people often misremember many features of the stories, often distorting information based on their expectations about what should have happened (Box 65–1). Forgetting and distortion can provide important insights into the workings of memory.

Daniel Schacter classified memory's imperfections into seven basic categories, called "the seven sins of memory": transience, absent-mindedness, blocking, misattribution, suggestibility, bias, and persistence. Here we focus on six of these.

Absent-mindedness results from the lack of attention to immediate experience. Absent-mindedness during encoding is a likely source of common memory failures such as forgetting where one recently placed an object. Absent-mindedness also occurs when we forget to carry out a particular task such as picking up groceries on the way home from the office, even though we initially encoded the relevant information. Little is known about the neural bases of absent-mindedness.

Blocking refers to temporary inaccessibility of information stored in memory. People often have partial awareness of a sought-after word or image but are nonetheless unable to recall it accurately or completely. People sometimes feel that a blocked word is on "the tip of the tongue"—we are aware of the initial letter of the word, the number of syllables in it, or a like-sounding word. Determining which information is correct and which is incorrect requires a great deal of conscious effort.

In an fMRI study Anat Maril and her colleagues scanned people while they tried to recall the names of people or places in response to cues. When they entered a tip-of-the-tongue state, brain regions that have been implicated in cognitive tasks—the anterior cingulate and the right dorsolateral prefrontal cortex—showed intense activity. This activity likely reflects a subject's attempts to sort out correct from incorrect information and to resolve the memory block.

Absent-mindedness and blocking are sins of omission: At a moment when we need to remember information, it is inaccessible. However, memory is also

characterized by sins of commission, situations in which some form of memory is present but wrong.

Misattribution refers to the association of a memory with an incorrect time, place, or person. False recognition, a type of misattribution, occurs when individuals report that they "remember" items or events that never happened. Such false memories have been documented in controlled experiments where people claim to have seen or heard words or objects that had not been presented previously but are similar in meaning or appearance to what was actually presented. Studies using PET and fMRI have shown that the hippocampus has similar levels of activity during both true and false recognition, which may be one reason why false memories sometimes feel like real ones.

Suggestibility refers to the tendency to incorporate external information into memory, usually as a result of leading questions or suggestions. Research using hypnotic suggestion indicates that various kinds of false memories can be implanted in highly suggestible individuals, such as remembering hearing loud noises at night. Studies with young adults have also shown that repeated suggestions to imagine a childhood experience can produce memories of episodes that never occurred. These findings are important theoretically because they highlight that memory is not simply a "playback" of past experiences. Despite these important theoretical and practical implications, next to nothing is known about the neural bases of suggestibility.

Bias refers to distortions and unconscious influences on memory that reflect one's general knowledge and beliefs. People often misremember the past to make it consistent with what they presently believe, know, or feel. As with suggestibility, however, almost nothing is known about the brain mechanisms of bias.

Persistence refers to obsessive memory, constant remembering of information or events that we might want to forget. Neuroimaging studies have illuminated some neurobiological factors that contribute to persistent emotional memories. For example, Larry Cahill and collaborators performed PET scans of subjects viewing a sequence of slides depicting an emotional story. The key results concerned activity in the amygdala, the almond-shaped structure located near the hippocampus and long known to be involved in emotional processing (see Chapter 48). The level of recall of the emotional components of the story was highly correlated with the level of activity in the amygdala during presentation of the story. This and related studies implicate the amygdala in the encoding and retrieval of emotionally charged experiences that can repeatedly intrude into consciousness.

Although persistence can be disabling, it also has adaptive value. The persistence of memories of disturbing experiences increases the likelihood that we will recall information about arousing or traumatic events at times when it may be crucial for survival.

Indeed, many memory imperfections may have adaptive value. For example, although the various forms of forgetting (transience, absent-mindedness, and blocking) can be annoying, a memory system that automatically retains every detail of every experience could result in an overwhelming clutter of useless trivia. This is exactly what happened in the fascinating case of Shereshevski, a mnemonist studied by the Russian neuropsychologist Alexander Luria. Shereshevski was filled with highly detailed memories of his past experiences and was unable to generalize or to think at an abstract level. A healthy memory system does not encode, store, and retrieve the details of every experience. Thus transience, absent-mindedness, or blocking allows us to avoid the unfortunate fate of Shereshevski.

An Overall View

We began this chapter by noting three key principles: (1) several different forms of learning and memory can be distinguished behaviorally, (2) memory can be analyzed in terms of discrete operations (encoding, storage, consolidation, and retrieval), and (3) imperfections and errors in remembering can provide telltale clues about learning and memory.

Considerable evidence supports the first principle, that there are different forms of memory, and we are learning that each involves different regions or combinations of regions in the brain. Thus working memory, which maintains goal-relevant information for short periods, has several neural components. Explicit memory involves the encoding and retrieval of two classes of knowledge: episodic memory, which represents personal experiences, and semantic memory, which represents general knowledge and facts. Explicit memory is typically retrieved deliberately and with some awareness that one is engaged in an act of remembering.

Implicit memory includes forms of perceptual and conceptual priming, as well as the learning of motor and perceptual skills and habits. It tends to be inflexible and expressed in the performance of tasks without conscious awareness. Implicit memory flows automatically in the course of perceiving, thinking, and acting.

Considerable progress also has been made concerning our second principle, that memory involves discrete encoding, storage, consolidation, and retrieval processes. Encoding of new memories depends critically on contributions from specific regions within the cortex and medial temporal lobe as shown most clearly in recent studies using fMRI.

The initiation of long-term storage of explicit memory requires the temporal lobe system, as highlighted by studies of amnesic patients such as H.M. Consolidation processes stabilize stored representations, rendering explicit memories no longer dependent on the medial temporal lobe. Retrieval of episodic memory involves the medial temporal lobe, as well as frontal and parietal cortices. Implicit memory, in contrast, involves a wide variety of brain regions, most often cortical areas that support the specific perceptual, conceptual, or motor systems recruited to process a stimulus or perform a task.

The third principle, that the past can be forgotten or distorted, is based on studies demonstrating that memory is not a faithful record of all details of every experience. Retrieved memories are the result of a complex interplay among various brain regions, and can be reshaped over time by multiple influences. Various forms of forgetting and distortion tell us much about the flexibility of memory that allows the brain to adapt to the physical and social environment.

Cellular Mechanisms of Implicit Memory Storage and the Biological Basis of Individuality

Storage of Implicit Memory Involves Changes in the Effectiveness of Synaptic Transmission

Habituation Results from an Activity-Dependent Presynaptic Depression of Synaptic Transmission

Sensitization Involves Presynaptic Facilitation of Synaptic Transmission

Classical Conditioning of Fear Involves Coordinated Pre- and Postsynaptic Facilitation of Synaptic Transmission

Long-Term Storage of Implicit Memory Involves Changes in Chromatin Structure and Gene Expression Mediated by the cAMP-PKA-CREB Pathway

Cyclic AMP Signaling Has a Role in Long-Term Sensitization

Long-Term Synaptic Facilitation Is Synapse Specific

Long-Term Facilitation Requires a Prion-Like Protein Regulator of Local Protein Synthesis for Maintenance

Classical Fear Conditioning in Flies Uses the cAMP-PKA-CREB Pathway

Memory for Learned Fear in Mammals Involves the Amygdala

Habit Learning and Memory Require the Striatum

Learning-Induced Changes in the Structure of the Brain Contribute to the Biological Basis of Individuality

An Overall View

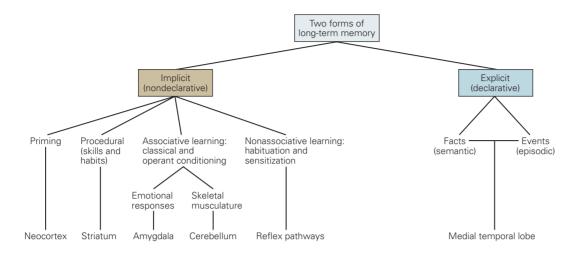

HROUGHOUT THIS BOOK WE HAVE EMPHASIZED that all behavior is a function of the brain and that malfunctions of the brain produce characteristic

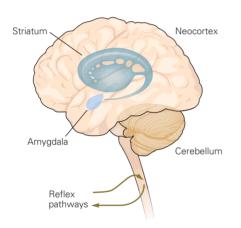

disturbances of behavior. Behavior is also shaped by experience. How does experience act on the neural circuits of the brain to change behavior? How is new information acquired by the brain and, once acquired, how is it remembered?

In the previous chapter we saw that memory is not a single process but has at least two major forms. Implicit memory operates unconsciously and automatically, as in the memory for habits and perceptual and motor skills, whereas explicit memory operates consciously, as in the memory for people, places, and objects. Long-term storage of explicit memory begins in the hippocampus and the medial temporal lobe of the neocortex, whereas long-term storage of implicit memory requires a family of structures: the neocortex for priming, the striatum for skills and habits, the amygdala for learned fear, the cerebellum for learned motor skills, and certain reflex pathways for nonassociative learning such as habituation and sensitization (Figure 66–1).

Over time, explicit memories are transferred to different regions of the neocortex. In addition, many cognitive, motor, and perceptual skills that we initially store in explicit memory ultimately become so ingrained with practice that they become stored as implicit memory.

The transference from explicit to implicit memory and the difference between them is dramatically demonstrated in the case of the English musician and conductor Clive Waring, who in 1985 sustained a viral infection of his brain (herpes encephalitis) that affected the hippocampus and temporal cortex. Waring was left with a devastating loss of memory for events or people he had encountered even a minute or two earlier.

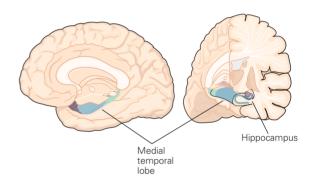

Figure 66–1 Two forms of long-term memory involve different brain systems. Implicit memory involves the neocortex, striatum, amygdala, cerebellum, and in the simplest cases the

reflex pathways themselves. Explicit memory requires the medial temporal lobe and the hippocampus, as well as certain areas of neocortex (not shown).

Yet he could still read music, perform on the piano, and conduct a chorale. Under these circumstances it was clear that many aspects of his basic personality—the biological basis of his individuality—were still intact. Once a performance was completed, however, he could not remember a thing about it.

Similarly, William deKooning, the abstract expressionist painter, developed Alzheimer disease and severe disturbances of explicit memory. As the disease progressed and his memory for people, places, and objects deteriorated, he nevertheless continued to produce important and interesting paintings. This aspect of his creative personality was relatively untouched.

In this chapter we examine the cellular and molecular mechanisms that underlie implicit memory in

invertebrate and vertebrate animals. In the next chapter we examine the biology of explicit memory storage in mammals.

Storage of Implicit Memory Involves Changes in the Effectiveness of Synaptic Transmission

Studies of elementary forms of implicit learning—habituation, sensitization, and classical conditioning—provided the groundwork for understanding the neural mechanisms of memory storage. Such learning has been analyzed in simple invertebrates and in a variety of vertebrate reflexes, such as the flexion reflexes, fear

responses, and the eye blink. These simple forms of implicit learning involve changes in the effectiveness of the synaptic pathways that mediate the behavior.

Habituation Results from an Activity-Dependent Presynaptic Depression of Synaptic Transmission

Habituation is the simplest form of implicit learning. It occurs, for example, when an animal learns to ignore a novel stimulus. An animal reacts to a new stimulus with a series of orienting responses. If the stimulus is neither beneficial nor harmful, the animal learns to ignore it after repeated exposure.

The physiological basis of habituation was first investigated by Charles Sherrington while studying posture and locomotion in the cat. Sherrington observed a decrease in the intensity of certain reflexes in response to repeated electrical stimulation of the motor pathways. He suggested that this decrease, which he called habituation, is caused by diminished synaptic effectiveness in the stimulated pathways. Habituation was later investigated at the cellular level by Alden Spencer and Richard Thompson. They found close cellular and behavioral parallels between habituation of a spinal flexion reflex in cats (the withdrawal of a limb from a noxious stimulus) and habituation of more complex human behaviors. They showed that during habituation the strength of the input from local excitatory interneurons onto motor neurons in the spinal cord decreased. Connections to interneurons from sensory neurons innervating the skin were unaffected.

Because the organization of interneurons in the vertebrate spinal cord is quite complex, it was difficult to analyze further the cellular mechanisms of habituation in the flexion reflex. Progress required a simpler system. The marine mollusk *Aplysia californica*, which has a simple nervous system of about 20,000 central neurons, proved to be an excellent system for studying implicit forms of memory.

Aplysia has a repertory of defensive reflexes for withdrawing its respiratory gill and siphon, a small fleshy spout above the gill used to expel seawater and waste (Figure 66–2A). These reflexes are similar to the withdrawal reflex of the leg studied by Spencer and Thompson. Mild touching of the siphon elicits reflex withdrawal of both the siphon and gill. With repeated stimulation these reflexes habituate. As we shall see, these responses can also be dishabituated, sensitized, and classically conditioned.

The neural circuit mediating the gill-withdrawal reflex in *Aplysia* has been studied in detail. Touching the siphon excites a population of mechanoreceptor sensory neurons that innervate the siphon. The release of

glutamate from sensory neuron terminals generates fast excitatory postsynaptic potentials (EPSPs) in interneurons and motor cells. The EPSPs from the sensory cells and interneurons summate on motor cells both temporally and spatially, causing them to discharge strongly, thereby producing vigorous withdrawal of the gill. If the stimulus is repeated, the monosynaptic EPSPs produced by sensory neurons in both interneurons and motor cells progressively decrease, paralleling the habituation of gill withdrawal. In addition, repeated stimulation also leads to a decrease in the strength of synaptic transmission from the excitatory interneurons to the motor neurons; the net result is that the reflex response diminishes (Figure 66–2B,C).

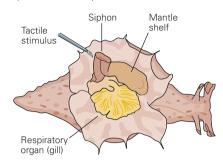

What reduces the effectiveness of synaptic transmission between the sensory neurons and their post-synaptic cells during repeated stimulation? Quantal analysis revealed that the amount of glutamate released from presynaptic terminals of sensory neurons decreases. That is, fewer synaptic vesicles are released with each action potential in the sensory neuron; the sensitivity of the postsynaptic glutamate receptors does not change. Because the reduction in transmission occurs in the activated pathway itself and does not require another modulatory cell, the reduction is referred to as *homosynaptic depression*. This depression lasts many minutes.

An enduring change in the functional strength of synaptic connections thus constitutes the cellular mechanism mediating short-term habituation. As change of this type occurs at several sites in the gill-withdrawal reflex circuit, memory is distributed and stored throughout the circuit. Depression of synaptic transmission by sensory neurons, interneurons, or both is a common mechanism underlying habituation of escape responses of crayfish and cockroaches as well as startle reflexes in vertebrates.

How much can the effectiveness of a synapse change and how long can the change last? In *Aplysia* a single session of 10 stimuli leads to short-term habituation of the withdrawal reflex lasting minutes. Four sessions separated by periods ranging from several hours to 1 day produce long-term habituation, lasting as long as 3 weeks (Figure 66–3).

Anatomical studies indicate that long-term habituation is caused by a decrease in the number of synaptic contacts between sensory and motor neurons. In naïve animals 90% of the sensory neurons make physiologically detectable connections with identified motor neurons. In contrast, in animals trained for long-term habituation the incidence of connections is reduced to 30%; the reduction in number of synapses persists for a week and does not fully recover even 3 weeks later.

A Experimental setup

B Gill-withdrawal reflex circuit

C Habituation

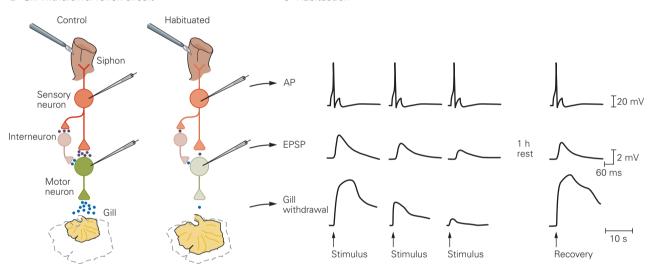

Figure 66–2 Short-term habituation of the gill-withdrawal reflex of the marine snail *Aplysia*.

A. A dorsal view of *Aplysia* illustrates the respiratory organ (gill) and the mantle shelf, which ends in the siphon, a fleshy spout used to expel seawater and waste. Touching the siphon elicits the gill-withdrawal reflex. Repeated stimulation leads to habituation.

B. This simplified circuit shows key elements of the gill-withdrawal reflex as well as sites involved in habituation. Approximately 24 mechanoreceptor neurons in the abdominal ganglion innervate the siphon skin. These sensory cells make excitatory synapses onto a cluster of six motor neurons that innervate the gill as well as on interneurons that modulate the firing of the motor neurons. (For simplicity only one of each type of neuron is illustrated here.) Touching the siphon leads to

withdrawal of the gill (dashed outline shows original gill size; solid outline shows maximal withdrawal).

C. Repeated stimulation of the siphon sensory neuron (top traces) leads to a progressive depression of synaptic transmission between the sensory and motor neurons, seen as a decrease in size of the motor neuron EPSP with no change in the action potential (AP) in the presynaptic sensory neuron. In a separate experiment repeated stimulation of the siphon results in a decrease in gill withdrawal (habituation). One hour after repetitive stimulation both the EPSP and gill withdrawal have recovered. Habituation is now known to involve a decrease in transmitter release at many synaptic sites throughout the reflex circuit (part B). (Adapted, with permission, from Pinsker et al. 1970; Castellucci and Kandel 1974.)

As we shall see later, long-term sensitization of synaptic transmission is associated with an increase in the number of synapses between sensory and motor neurons.

Not all synapses are equally modifiable. In *Aplysia* the strength of some synapses rarely changes, even with repeated activation. In synapses specifically involved in learning (such as the connections between sensory and motor neurons in the withdrawal reflex

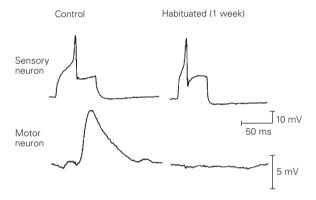

circuit) a relatively small amount of training can produce large and enduring changes in synaptic strength.

Sensitization Involves Presynaptic Facilitation of Synaptic Transmission

When an animal repeatedly encounters a harmless stimulus, its responsiveness to the stimulus habituates.

In contrast, with a *harmful* stimulus the animal typically learns fear; it responds vigorously not only to the harmful stimulus but also to other concurrent stimuli, even harmless ones. As a result, defensive reflexes for withdrawal and escape become heightened. This enhancement of reflex responses is called *sensitization*.

A Depression of synaptic potentials by long-term habituation

B Inactivation of synaptic connections by long-term habituation

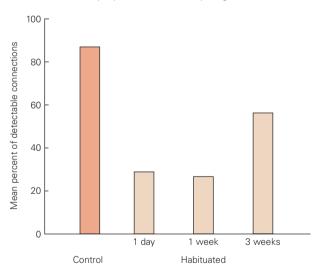

Figure 66–3 Long-term habituation of the gill-withdrawal reflex in *Aplysia*. (Adapted, with permission, from Castellucci, Carew, and Kandel 1978.)

A. Comparison of the action potentials and synaptic potentials in sensory and motor neurons, respectively, in an untrained animal (control) and one that has been subjected to long-term habituation. In the habituated animal 1 week after training no synaptic potential occurs in the motor neuron in response to the sensory neuron action potential.

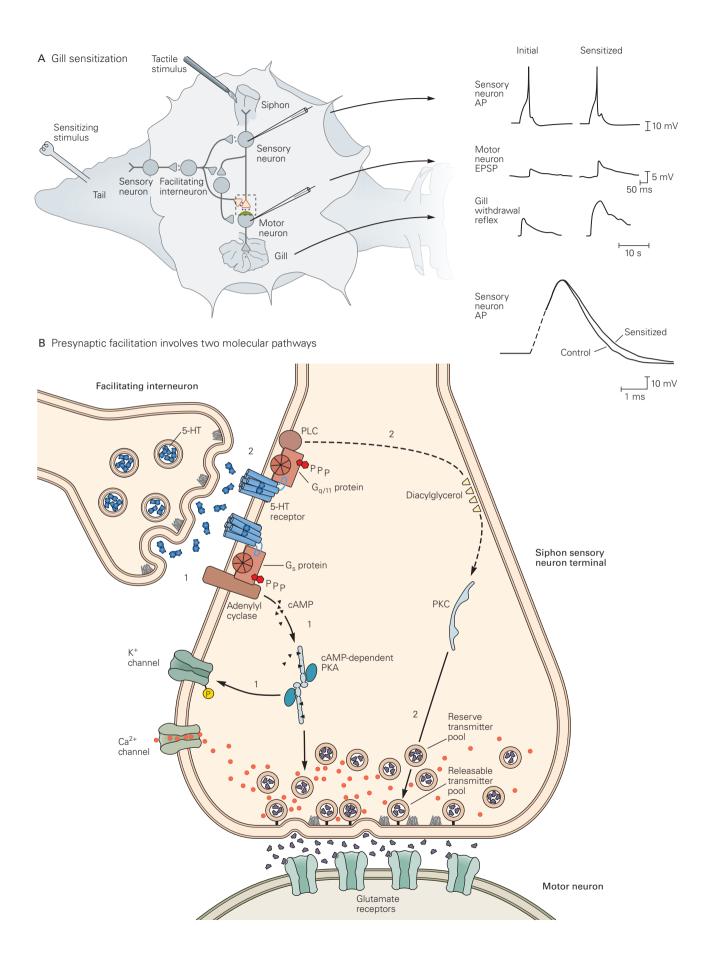

B. The mean percentage of sensory neurons making physiologically detectable connections with motor neurons in habituated animals is decreased at three points in time after long-term habituation training.

Like habituation, sensitization can be transient or long lasting. A single shock to the tail of an *Aplysia* produces short-term sensitization of the gill-withdrawal reflex that lasts minutes; five or more shocks to the tail produce sensitization lasting days to weeks. Tail shock is also sufficient to overcome the effects of habituation and enhance a habituated gill-withdrawal reflex, a process termed *dishabituation*.

Sensitization and dishabituation result from an enhancement in synaptic transmission at several connections in the neural circuit of the gill-withdrawal reflex, including the connections made by sensory neurons with motor neurons and interneurons—the same synapses depressed by habituation (Figure 66–4A). Typically, modifiable synapses can be regulated bidirectionally, participate in more than one type of learning, and store more than one type of memory. The bidirectional synaptic changes that underlie habituation and sensitization are the result of different cellular mechanisms. In Aplysia the same synapses that are weakened by habituation through a homosynaptic process can be strengthened by sensitization through a heterosynaptic process that depends on modulatory interneurons activated by the harmful stimulus to the tail.

At least three groups of modulatory interneurons are involved in sensitization. The best studied use serotonin as a transmitter. The serotonergic interneurons form synapses on many regions of the sensory neurons, including axo-axonic synapses on the presynaptic terminals of the sensory cells. The serotonin released from the interneurons after a single tail shock binds to a type of receptor in the sensory neurons that is coupled to a stimulatory G protein that increases the activity of adenylyl cyclase. This action produces the second messenger cyclic adenosine monophosphate (cAMP), which in turn activates the cAMP-dependent protein kinase (PKA) (see Chapter 11). Serotonin also activates a second type of G protein-coupled receptor that leads to the hydrolysis of phospholipids and the activation of protein kinase C (PKC).

The protein phosphorylation mediated by PKA and PKC enhances the release of transmitter from sensory neurons through at least two mechanisms (Figure 66–4B). In one action PKA phosphorylates a K⁺ channel, causing it to close. This broadens the action potential and thus enhances Ca²⁺ influx through voltage-gated Ca²⁺ channels, which in turn enhances transmitter release. In a second action protein phosphorylation through PKC enhances the functioning of the release machinery directly. Presynaptic facilitation in response to release of serotonin by a tail shock lasts for a period of many minutes. Repeated noxious stimuli can strengthen synaptic activity for days.

Classical Conditioning of Fear Involves Coordinated Pre- and Postsynaptic Facilitation of Synaptic Transmission

Classical conditioning is a more complex form of learning. Rather than learning about the properties of one stimulus, as in habituation and sensitization, the animal learns to associate one type of stimulus with another. As described in Chapter 65, an initial weak conditioned stimulus (such as the ringing of a bell) becomes highly effective in producing a response when paired with a strong unconditioned stimulus (such as presentation of food). In reflexes that can be enhanced by both classical conditioning and sensitization, like the defensive withdrawal reflexes of *Aplysia*, classical conditioning results in greater and longer-lasting enhancement.

For classical conditioning of the *Aplysia* gill-withdrawal reflex, a weak touch to the siphon serves as the conditioned stimulus while a strong shock to the tail serves as the unconditioned stimulus. When the gill withdrawal reflex is classically conditioned, gill withdrawal in response to siphon stimulation alone is greatly enhanced. This enhancement is even more dramatic than the enhancement produced in an unpaired pathway by tail shock alone (sensitization). In classical conditioning the timing of the conditioned and unconditioned stimuli is critical. To be effective, the conditioned stimulus (siphon touch) must *precede* (and predict) the unconditioned stimulus (tail shock), often within an interval of about 0.5 seconds (Figure 66–5).

The convergence in individual sensory neurons of the signals initiated by the conditioned and

unconditioned stimuli is critical. A strong shock to the tail excites serotonergic interneurons that form synapses on presynaptic terminals of the siphon sensory neurons, resulting in presynaptic facilitation associated with sensitization (Figure 66–5A). However, when the tail shock (unconditioned stimulus) immediately follows a slight tap on the siphon (conditioned stimulus), the serotonin from the interneurons produces even greater presynaptic facilitation, a process termed *activity-dependent facilitation* (Figure 66–5B).

How does this work? During conditioning the modulatory interneurons activated by tail shock release serotonin shortly *after* siphon touch has triggered an action potential in the sensory neurons. The action potential triggers an influx of Ca²⁺ into the sensory neuron's presynaptic terminals, the Ca²⁺ binds to calmodulin, and the complex in turn binds to adenylyl cyclase. This primes the adenylyl cyclase so that it responds more vigorously to the serotonin released following the unconditioned stimulus at the tail. As a result, the production of cAMP is enhanced, which increases the amount of presynaptic facilitation. If the order of stimuli is reversed so that serotonin release precedes Ca²⁺ influx in the presynaptic terminals, there is no potentiation and no classical conditioning.

Thus the cellular mechanism of classical conditioning in the monosynaptic pathway of the withdrawal reflex is largely an elaboration of the mechanism of sensitization, with the added feature that the adenylyl cyclase serves as a *coincidence detector* in the presynaptic sensory neuron, recognizing the temporal order of

Figure 66–4 (Opposite) Short-term sensitization of the gill-withdrawal reflex in *Aplysia*.

A. Sensitization of the gill-withdrawal reflex is produced by applying a noxious stimulus to another part of the body, such as the tail. A shock to the tail activates tail sensory neurons that excite facilitating (modulatory) interneurons, which form synapses on the cell body and terminals of the mechanoreceptor sensory neurons that innervate the siphon. Through these axo-axonic synapses the modulatory interneurons enhance transmitter release from the siphon sensory neurons onto their postsynaptic gill motor neurons (presynaptic facilitation), thus enhancing gill withdrawal. Presynaptic facilitation results, in part, from a prolongation of the sensory neuron action potential (bottom traces). (Adapted, with permission, from Pinsker et al. 1970; Klein and Kandel 1980.)

B. Presynaptic facilitation in the sensory neuron is thought to occur by means of two biochemical pathways. The diagram shows details of the synaptic complex in the **dashed box** in part A.

Pathway 1: A facilitating interneuron releases serotonin (5-HT), which binds to metabotropic receptors in the sensory neuron terminal. This action engages a G protein (\mathbf{G}_s), which in turn increases the activity of adenylyl cyclase. The adenylyl cyclase converts ATP to cAMP, which binds to the regulatory subunit of PKA, thus activating its catalytic subunit. The catalytic subunit phosphorylates certain K⁺ channels, thereby closing the channels and decreasing the outward K⁺ current. This prolongs the action potential, thus increasing the influx of Ca^{2+} through voltage-gated Ca^{2+} channels and thereby augmenting transmitter release.

Pathway 2: Serotonin binds to a second class of metabotropic receptor that activates the $G_{q/11}$ class of G protein that enhances the activity of phospholipase C (PLC). The PLC activity leads to production of diacylglycerol, which activates protein kinase C (PKC). Phosphorylation of presynaptic proteins by PKC results in the mobilization of vesicles containing glutamate from a reserve pool to a releasable pool at the active zone, increasing the efficiency of transmitter release.

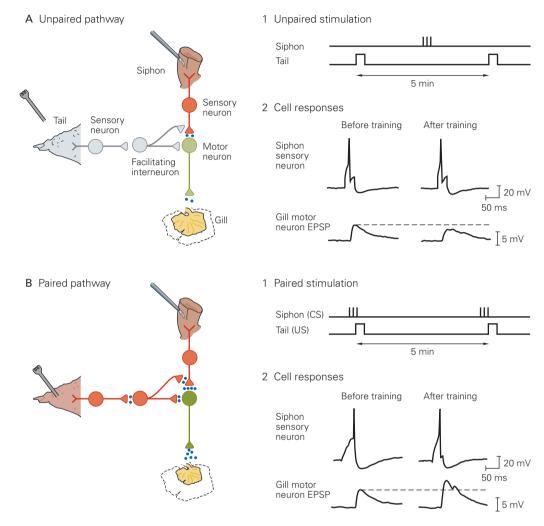

Figure 66–5 Classical conditioning of the gill-withdrawal reflex in *Aplysia*. (Adapted, with permission, from Hawkins et al. 1983.)

A. The siphon is stimulated by a light touch and the tail is shocked, but the two stimuli are not paired in time. The tail shock excites facilitatory interneurons that form synapses on the presynaptic terminals of sensory neurons innervating the mantle shelf and siphon. This is the mechanism of sensitization. 1. The pattern of unpaired stimulation during training.

2. Under these conditions the size of the motor neuron EPSP is only weakly facilitated by the tail shock. In this example the EPSP actually decreases slightly despite the tail shock because repeated unpaired stimulation of the siphon leads to synaptic depression.

- **B.** The tail shock is paired with stimulation of the siphon.
- 1. The siphon is touched (conditioned stimulus or CS)

immediately prior to shocking the tail (unconditioned stimulus or US). As a result, the siphon sensory neurons are primed to be more responsive to input from the facilitatory interneurons in the unconditioned pathway. This is the mechanism of classical conditioning; it both amplifies the response of the conditioned pathway and restricts the amplification to that pathway.

2. Recordings of EPSPs in an identified motor neuron produced by the siphon sensory neurons before training and one hour after training. After training the EPSP in the motor neuron produced by paired sensory input is considerably greater than either the EPSP before training or the EPSP following unpaired tail shock (shown in part A2). This produces a more vigorous gill withdrawal.

the physiological representations of both the unconditioned stimulus (tail shock) and conditioned stimulus (siphon touch).

In addition to the presynaptic component of activity-dependent facilitation, a postsynaptic component is triggered by Ca⁺ influx into the motor neuron when it is highly excited by the siphon sensory neurons. The properties of this postsynaptic mechanism are similar to those of long-term potentiation of synaptic transmission in the mammalian brain (discussed later in this chapter and in Chapter 67).

Long-Term Storage of Implicit Memory Involves Changes in Chromatin Structure and Gene Expression Mediated by the cAMP-PKA-CREB Pathway

Cyclic AMP Signaling Has a Role in Long-Term Sensitization

In all forms of learning practice makes perfect. Repeated experience converts short-term memory into a long-term form. In *Aplysia* the form of long-term memory that has been most intensively studied is long-term sensitization. Like the short-term form, long-term sensitization of the gill-withdrawal reflex involves changes in the strength of connections at several synapses, including those between sensory and motor neurons. However, it also involves the growth of new synaptic connections.

Five spaced training sessions (or repeated applications of serotonin) over approximately 1 hour produce long-term sensitization and long-term synaptic facilitation lasting 1 or more days; continued spaced training over several days produces sensitization that persists for 1 or more weeks. Long-term sensitization, like the short-term form, requires protein phosphorylation that is dependent on increased levels of cAMP (Figure 66–6).

The conversion of short-term memory into long-term memory, called *consolidation*, requires synthesis of messenger RNAs and proteins in the neurons in the circuit. Thus specific gene expression is required for long-term memory. The transition from short-term to long-term memory depends on the prolonged rise in cAMP that follows repeated applications of serotonin. This leads to prolonged activation of PKA, allowing the catalytic subunit of the kinase to translocate into the nucleus of the sensory neurons. It also leads indirectly to activation of a second protein kinase, the mitogenactivated protein kinase (MAPK), a kinase commonly associated with cellular growth (see Chapter 11).

Within the nucleus the catalytic subunit of PKA phosphorylates and thereby activates the transcription factor CREB-1 (*c*AMP *response element binding protein* 1), which binds a promoter element called CRE (*c*AMP *recognition element*) (Figures 66–6 and 66–7).

To turn on gene transcription, phosphorylated CREB-1 recruits a transcriptional coactivator, CREBbinding protein (CBP), to the promoter region. CBP has two important properties that facilitate transcriptional activation: it recruits RNA polymerase II to the promoter, and it functions as an acetyltransferase, adding acetyl groups to certain lysine residues on its substrate proteins. One of the most important substrates of CBP are the histone proteins, which are components of nucleosomes, the fundamental building blocks of chromatin. The histones contain a series of positively charged basic residues that strongly interact with the negatively charged phosphates of DNA. This interaction causes DNA to become tightly wrapped around the nucleosomes, much like string is wrapped around a spool, thereby preventing necessary transcription factors from accessing their gene targets.

The binding of CBP to CREB-1 leads to histone acetylation, which causes a number of important structural and functional changes at the nucleosome level. For example, acetylation neutralizes the positive charge of lysine residues in the histone tail domains, decreasing the affinity of histones for DNA. Also, specific classes of transcriptional activators can bind to acetylated histones and facilitate the repositioning of nucleosomes at the promoter region. Together these and other types of chromatin modifications serve to regulate the accessibility of chromatin to the transcriptional machinery, and thus enhance the ability of a gene to be transcribed. As we will see in Chapter 67, a mutation in the gene encoding CBP underlies Rubinstein-Taybi syndrome, a disorder associated with mental retardation.

The turning on of transcription by PKA also depends on its ability to indirectly activate the MAPK pathway (see Chapter 11). MAPK phosphorylation of the transcription factor CREB-2 relieves an inhibitory action of CREB-2 on transcription (Figure 66–6B). The combined effects of CREB-1 activation and relief of CREB-2 repression induces a cascade of new gene expression important for learning and memory (Figure 66–7).

The presence of both a repressor (CREB-2) and an activator (CREB-1) of transcription at the first step in long-term facilitation suggests that the threshold for long-term memory storage can be regulated. Indeed, we see in everyday life that the ease with which short-term memory is transferred into long-term memory varies greatly with attention, mood, and social context.

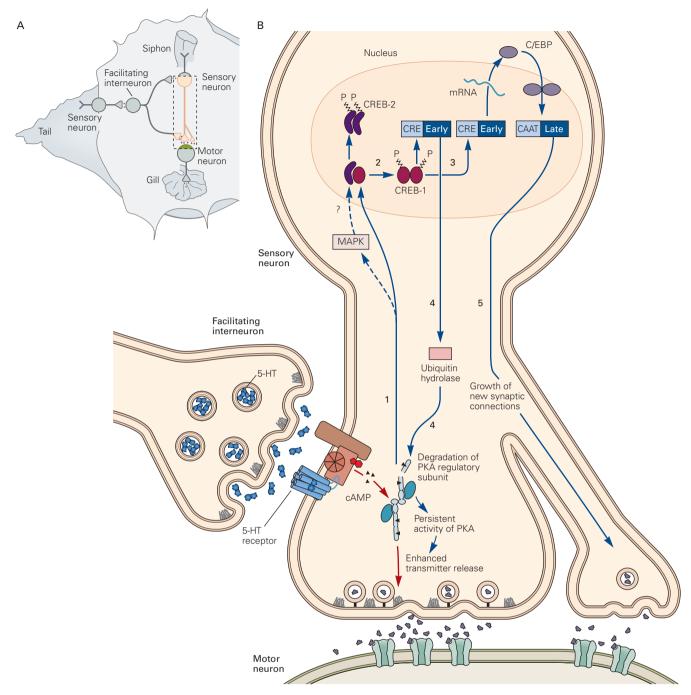

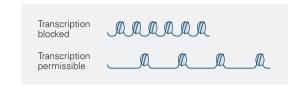

Figure 66–6 Long-term sensitization involves synaptic facilitation and the growth of new synaptic connections.

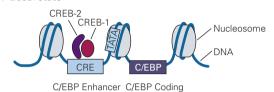

A. Long-term sensitization of the gill-withdrawal reflex of *Aplysia* following repeated tail shocks involves long-lasting facilitation of transmitter release at the synapses between sensory and motor neurons.

B. Long-term sensitization of the gill-withdrawal reflex leads to persistent activity of PKA, resulting in the growth of new synaptic connections. Repeated tail shock leads to more pronounced elevation of cAMP, producing long-term facilitation (lasting 1 or more days) that outlasts the increase in cAMP and recruits the synthesis of new proteins. This inductive mechanism is initiated by translocation of PKA to the nucleus (pathway 1), where PKA phosphorylates the transcriptional activator CREB-1 (cAMP response element binding protein 1)

(pathway 2). CREB-1 binds cAMP regulatory elements (CRE) located in the upstream region of several cAMP-inducible genes, activating gene transcription (pathway 3). PKA also activates the mitogen-activated protein kinase (MAPK), which phosphorylates the transcriptional repressor CREB-2 (cAMP response element binding protein 2), thus removing its repressive action. One gene activated by CREB-1 encodes a ubiquitin hydrolase, a component of a specific ubiquitin proteasome that leads to the proteolytic cleavage of the regulatory subunit of PKA, resulting in persistent activity of PKA, even after cAMP has returned to its resting level (pathway 4). CREB-1 also activates the expression of the transcription factor C/EBP, which leads to expression of a set of unidentified proteins important for the growth of new synaptic connections (pathway 5).

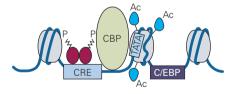

A Basal state

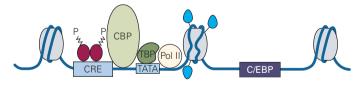

B 5-HT produces modifications in chromatin structure CREB-1 phosphorylation and exclusion of CREB-2

5-HT PKA

Recruitment of CBP and histone acetylation

Initiation of transcription by Pol II

mRNA elongation

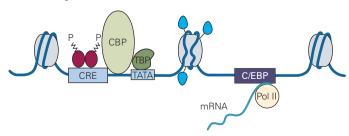

Figure 66–7 Regulation of histone acetylation by serotonin, CREB-1, and CBP.

A. Under basal conditions the activator CREB-1 (here in complex with CREB-2) occupies the binding site for CRE (cAMP recognition element) within the promoter region of its target genes. In the example shown here, CREB-1 binds to the CRE within the C/EBP promoter. In the basal state CREB-1 binding is not able to activate transcription because the TATA box, the core promoter region responsible for recruiting RNA polymerase II (Pol II) during transcription initiation, is inaccessible because the DNA is tightly bound to histone proteins in the nucleosome.

B. Serotonin (5-HT) activates PKA, which phosphorylates CREB-1 and indirectly enhances CREB-2 phosphorylation by MAPK, causing the repressor to dissociate from the promoter. This allows CREB-1 to form a complex at the promoter with CREB binding protein (CBP). Activated CBP acetylates specific lysine residues of the histones, causing them to bind less tightly to DNA. Along with other changes in chromatin structure, acetylation facilitates the repositioning of the nucleosome that previously blocked access of the Pol II complex to the TATA box. This repositioning allows Pol II to be recruited to initiate transcription of the C/EBP gene. (TBP, TATA binding protein).

Two of the genes expressed in the wake of CREB-1 activation and the consequential alteration in chromatin structure are important in the early development of long-term facilitation. One is a gene for ubiquitin carboxyterminal hydrolase. The other is a gene for a transcription factor, CAAT box enhancer binding protein (C/EBP), a component of a gene cascade necessary for synthesizing proteins needed for the growth of new synaptic connections (Figure 66–6, 66–7).

The hydrolase, which facilitates ubiquitin-mediated protein degradation (see Chapter 3), helps enhance activation of PKA. Protein kinase A is made up of four subunits; two regulatory subunits inhibit two catalytic subunits (see Chapter 11). With long-term training and the induction of the hydrolase, approximately 25% of the regulatory subunits are degraded in the sensory neurons. As a result, free catalytic subunits can continue to phosphorylate proteins important for the enhancement of transmitter release and the strengthening of synaptic connections, including CREB-1, long after cAMP has returned to its basal level (Figure 66–6B). Formation of a constitutively active enzyme is therefore the simplest molecular mechanism for long-term memory. With repeated training a secondmessenger kinase critical for short-term facilitation can remain persistently active for up to 24 hours without requiring a continuous activating signal.

The second and more enduring consequence of CREB-1 activation is the activation of the transcription factor C/EBP. This transcription factor forms both a homodimer with itself and a heterodimer with another transcription factor called *activating factor*. Together these factors act on downstream genes that trigger the growth of new synaptic connections that support long-term memory.

With long-term sensitization the number of presynaptic terminals in the sensory neurons in the gill-withdrawal circuit doubles (Figure 66–8). The dendrites of the motor neurons also grow to accommodate the additional synaptic input. Thus long-term structural changes in both post- and presynaptic cells increase the number of synapses.

Long-term habituation, in contrast, leads to *pruning* of synaptic connections. The long-term inactivation of the functional connections between sensory and motor neurons reduces the number of terminals of each sensory neuron by one-third (Figure 66–8A).

Long-Term Synaptic Facilitation Is Synapse Specific

A typical neuron in the mammalian brain makes 10,000 synapses with a wide range of target cells. It is therefore generally thought that long-term memory storage

should be synapse specific—that is, only those synapses that actively participate in learning should be enhanced. However, the finding that long-term facilitation involves gene expression—which occurs in the nucleus, an organelle that is far removed from a neuron's synapses—raises some fundamental questions regarding information storage.

Is long-term memory storage indeed synapse specific, or do the gene products recruited during long-term memory storage alter the strength of every presynaptic terminal in a neuron? And if long-term memory is synapse specific, what are the cellular mechanisms that enable the products of gene transcription to selectively strengthen just some synapses and not others?

Kelsey Martin and her colleagues addressed these questions regarding long-term facilitation by using a cell culture system consisting of an isolated *Aplysia* sensory neuron with a bifurcated axon that makes separate synaptic contacts with two motor neurons. The sensory neuron terminals on one of the two motor neurons were activated by focal pulses of serotonin, thus mimicking the neural effects of a shock to the tail. When only one pulse of serotonin was applied, those synapses showed short-term facilitation. The synapses on the second motor neuron, which did not receive serotonin, showed no change in synaptic transmission (Figure 66–9).

When five pulses of serotonin were applied to the same synapses, those synapses displayed both short-term and long-term facilitation, and new synaptic connections were formed with the motor neuron. Again the synapses that did not receive serotonin showed no enhancement of synaptic transmission (Figure 66–9B). Thus both short-term and long-term synaptic facilitation are synapse specific and manifested only by those synapses that receive the modulatory serotonin signal.

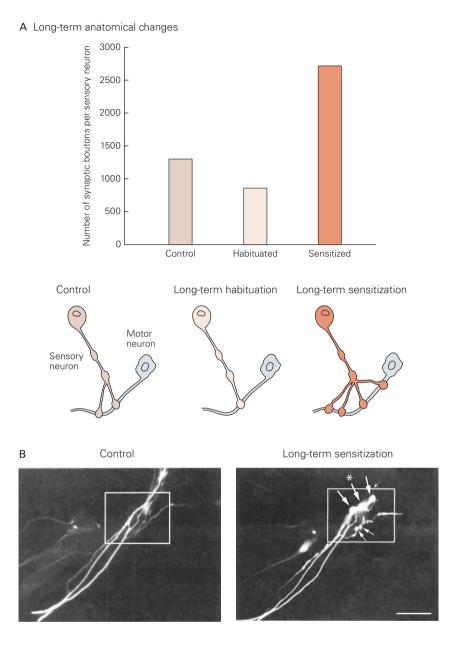

But how are the nuclear products able to enhance transmission at certain synapses only? Are the newly synthesized proteins somehow targeted to only those synapses that receive serotonin? Or are they shipped out to all synapses but used productively for the growth of new synaptic connections only at those synapses that have been activated—or marked—perhaps by only a single pulse of serotonin?

To test this question Martin and her colleagues again selectively applied five pulses of serotonin to the synapses made by the sensory neuron onto one of the motor neurons. This time, however, the synapses with the second motor neuron were simultaneously activated by a single pulse of serotonin (which by itself produces only short-term synaptic facilitation lasting

Figure 66–8 Long-term habituation and sensitization involve structural changes in the presynaptic terminals of sensory neurons.

A. Long-term habituation leads to a loss of synapses, and long-term sensitization leads to an increase in number of synapses. When measured either 1 day (shown here) or 1 week after training, the number of presynaptic terminals (or boutons) relative to control levels is increased in sensitized animals and reduced in habituated animals. The drawings below the graph illustrate changes in the number of synaptic contacts. Swellings or varicosities on sensory neuron processes are presynaptic terminals. (Adapted, with permission, from Bailey and Chen 1983.)

B. Fluorescence images of the axon of a sensory neuron contacting a motor neuron in culture before (left) and 1 day after (right) five brief exposures to serotonin. The resulting increase in varicosities simulates the synaptic changes associated with long-term sensitization. Prior to serotonin application no presynaptic varicosities are visible in the outlined area (control). After serotonin the growth of several new varicosities is apparent (arrows), indicative of formation of new synapses. Boutons can be seen at the arrows in the right, some of which contain a fully developed zone, identified by the asterisk, or have small, immature active zones. Scale bar = 50 μm. (Reproduced, with permission, from Glanzman, Kandel, and Schacher 1990.)

minutes). Under these conditions the single pulse of serotonin was sufficient to induce long-term facilitation and growth of new synaptic connections at the contacts between the sensory neuron and the second motor neuron. Thus application of the single pulse of serotonin onto the synapses at the second branch enabled those synapses to use the nuclear products produced in response to the five pulses of serotonin onto the synapses of the first branch, a process called *capture*.

These results suggest that newly synthesized gene products, both mRNAs and proteins, are delivered by

a fast axonal transport mechanism to all the synapses of a neuron but are functionally incorporated only at synapses that have been tagged or marked by previous synaptic activity.

For a synapse to use the new proteins and mRNAs for long-term facilitation, it must first be marked by serotonin. Although one pulse of serotonin at a synapse is insufficient to turn on new gene expression in the cell body, it is sufficient to allow that synapse to make productive use of new proteins generated in the soma in response to the five pulses of serotonin at another synapse. This idea, developed by Martin and

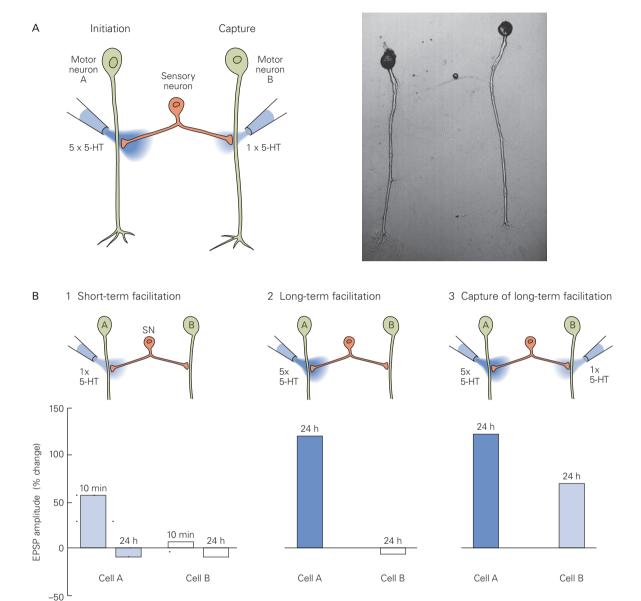

Figure 66–9 Long-term facilitation of synaptic transmission is synapse-specific. (Adapted, with permission, from Martin et al. 1997.)

A. The experiment uses a single presynaptic sensory neuron that contacts two postsynaptic motor neurons (A and B). The pipette on the left is used to apply five pulses of serotonin (5-HT) to a sensory neuron synapse with motor neuron A, initiating long-term facilitation at these synapses. The pipette on the right is used to apply one pulse of 5-HT to a sensory neuron synapse with motor neuron B, allowing this synapse to make use of (capture) new proteins produced in the cell body in response to the five pulses of 5-HT at the synapses with motor neuron A. The image at the right shows the actual appearance of the cells in culture.

B. 1. One pulse of 5-HT applied to the synapses with motor neuron A produces only short-term (10 min) facilitation of the excitatory postsynaptic potential (EPSP) in the neuron. By 24 hours the EPSP has returned to its normal size. There is no significant change in EPSP size in cell B. 2. Application of five pulses of 5-HT to the synapses with cell A produces long-term (24 hour) facilitation of the EPSP in that cell but no change in the size of the EPSP in cell B. 3. However, when five pulses of 5-HT onto the synapses with cell A are paired with a single pulse of 5-HT onto the synapses with cell B, cell B displays long-term facilitation and an increase in EPSP size after 24 hours.

her colleagues for *Aplysia* and independently by Frey and Morris for the hippocampus in rodents, is called *synaptic capture* or *synaptic tagging*.

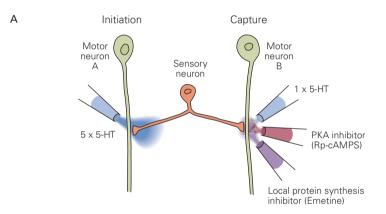

These findings raise the question, what is the nature of the synaptic mark that allows the capture of the gene products for long-term facilitation? When an inhibitor of PKA was applied locally to the synapses receiving the single pulse of serotonin, those synapses could no longer capture the gene products produced in response to the five pulses of serotonin (Figure 66–10). This indicates that phosphorylation mediated by PKA is required for capturing the long-term process.

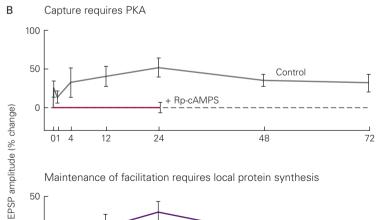

In the early 1980s Oswald Steward discovered that ribosomes, the machinery for protein synthesis, are situated locally at the synapse in addition to being present in the cell body. Martin examined the importance of local protein synthesis in long-term synaptic facilitation by applying a single pulse of serotonin together with an inhibitor of local protein synthesis onto one set of synapses while simultaneously applying five pulses of serotonin to the other set of synapses. Normally long-term facilitation and synaptic growth would persist for up to 72 hours in response to synaptic capture. In the presence of the protein synthesis inhibitor, synaptic capture could still generate long-term synaptic facilitation at the synapses exposed to only one pulse of serotonin for at least 24 hours (Figure 66–10B), but synaptic growth and facilitation at these synapses collapsed after 24 hours, indicating that the maintenance of learning-induced

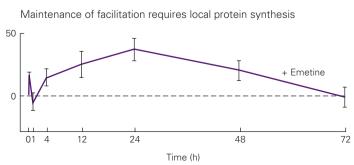

Figure 66–10 Long-term facilitation requires both cAMP-dependent phosphorylation and local protein synthesis. (Adapted, with permission, from Casadio et al., 1999.)

A. Five pulses of serotonin (5-HT) are applied to the synapses on motor neuron A and a single pulse is applied to those of cell B. Inhibitors of protein kinase A (Rp-cAMPS) or local protein synthesis (emetine) are applied to synapses on cell B.

B. Rp-cAMPS blocks the capture of long-term facilitation completely at the synapses on neuron B. Emetine has no effect on the capture of facilitation or the growth of new synaptic connections measured 24 hours after 5-HT application, but by 72 hours it fully blocks synaptic enhancement. The outgrowth of new synaptic connections is retracted and long-term facilitation decays after 1 day if capture is not maintained by local protein synthesis. (Rp-cAMPS, Rp-diastereomer of adenosine cyclic 3',5'-phosphorothioate.)

synaptic growth requires new local protein synthesis at the synapse.

Martin and her colleagues thus found that regulation of protein synthesis at the synapse plays a major role in controlling synaptic strength at the sensory-to-motor neuron connection in *Aplysia*. As we shall see in Chapter 67, local protein synthesis is also important for the later phases of long-term potentiation of synaptic strength in the hippocampus.

These findings indicate there are two distinct components of synaptic marking in *Aplysia*. The first component, lasting about 24 hours, initiates long-term synaptic plasticity and synaptic growth, requires transcription and translation in the nucleus, and recruits local PKA activity, but does not require local protein synthesis. The second component, which stabilizes the long-term synaptic change after 72 hours, requires local protein synthesis at the synapse. How might this local protein synthesis be regulated?

Long-Term Facilitation Requires a Prion-Like Protein Regulator of Local Protein Synthesis for Maintenance

The fact that mRNAs are translated at the synapse in response to marking of that synapse by one pulse of serotonin suggests that these mRNAs may initially be dormant and under the control of a regulator of translation recruited by serotonin. Joel Richter found that in Xenopus (frog) oocytes the maternal mRNAs have a short tail of adenine nucleotides, poly(A), at their 3' end and are silent until activated by the cytoplasmic polyadenylation element binding protein (CPEB), which binds to a site on mRNAs and recruits poly(A) polymerase, leading to the elongation of the poly(A) tail. Kausik Si and his colleagues found that serotonin increases the local synthesis of a novel, neuron-specific isoform of CPEB in Aplysia sensory neuron processes (Figure 66–11). The induction of CPEB is independent of transcription but requires new protein synthesis. Blocking CPEB locally at an activated synapse blocks the long-term maintenance of synaptic facilitation at the synapse but not its initiation and maintenance for 24 hours.

How might CPEB stabilize the late phase of longterm facilitation? Most biological molecules have a relatively short half-life (hours to days) compared to the duration of memory (days, weeks, even years). How then can the learning-induced alterations in the molecular composition of a synapse be maintained for such a long time? Most hypotheses rely on some type of self-sustained mechanism that can somehow modulate synaptic strength and synaptic structure. Si and his colleagues found that the neuronal isoform of *Aplysia* CPEB indeed appears to have self-sustaining properties that resemble those of prion proteins. Prions were discovered by Stanley Prusiner, who demonstrated that these proteins were the causative agents of Jacob-Creutzfeldt disease, a terrible neurodegenerative human disease, and of mad cow disease. Prion proteins can exist in a soluble form and an aggregated form that is capable of self-perpetuation. *Aplysia* CPEB also has two conformational states, a soluble form that is inactive and an aggregated form that is active. This switch involves an N-terminal domain of CPEB that is rich in glutamine, similar to prion domains in other proteins.

In a naïve synapse CPEB exists in the soluble, inactive state, and its basal level of expression is low. However, in response to serotonin the local synthesis of CPEB increases until a threshold concentration is reached that switches CPEB to the aggregated, active state, which is then capable of activating the translation of dormant mRNAs. Once the active state is established, it becomes self-perpetuating by recruiting soluble CPEB to aggregates. Dormant mRNAs, made in the cell body and distributed cell-wide, are translated only at synapses with active CPEB.

Because the activated CPEB is self-perpetuating, it could promote a self-sustaining, synapse-specific long-term molecular change and provide a mechanism for the stabilization of learning-related synaptic growth and the persistence of memory storage (Figure 66–11). This proposed mechanism, albeit self-perpetuating, is different from conventional prion mechanisms, which are pathogenic (the aggregated state of most prion proteins causes cell death). By contrast, CPEB is a new form of a prion-like protein. It is a functional prion; the active self-perpetuating form of the protein does not kill cells but rather has an important physiological function.

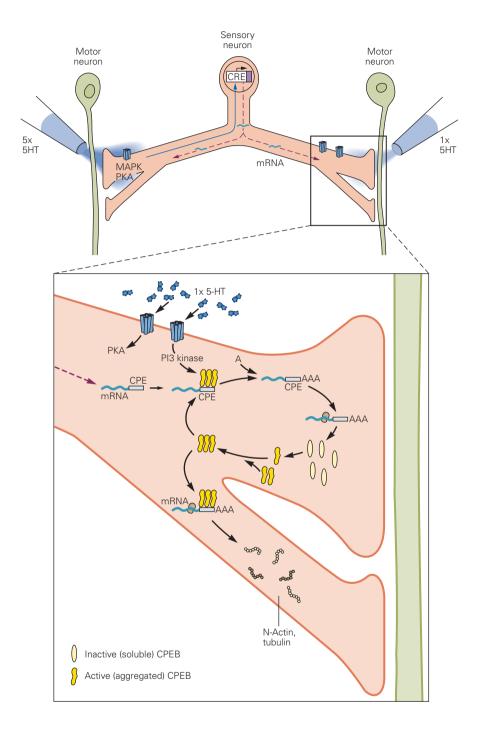

Classical Fear Conditioning in Flies Uses the cAMP-PKA-CREB Pathway

Do the mechanisms for implicit memory found in *Aplysia* have parallels in other animals? Studies on fear learning in both the fruit fly *Drosophila* and mouse indicate that the molecular mechanisms of implicit memory are conserved throughout evolution.

The fruit fly is particularly convenient for the study of implicit memory storage because its genome is easily manipulated and, as first demonstrated by Seymour Benzer and his colleagues, the fly can be classically conditioned.

In a typical classical conditioning paradigm an odor is paired with repeated electrical foot shocks. The extent of learning is then examined by allowing

Figure 66-11 CPEB may be a selfperpetuating switch of protein synthesis at axon terminals and synapsespecific growth. According to this model (based on Bailey, Kandel, and Si, 2004) five pulses of serotonin (5-HT) set up a signal that goes back to the nucleus to activate synthesis of mRNA. Newly transcribed mRNAs and newly synthesized proteins made in the cell body are then sent to all terminals by fast axonal transport. However, only those terminals that have been marked by exposure to at least one pulse of serotonin can use the proteins productively to grow new synapses and produce long-term facilitation. The marking of a terminal involves two components: (1) protein kinase A (PKA), which is necessary for the immediate synaptic growth initiated by the proteins transported to the terminals, and (2) phosphoinositide 3 kinase (PI3 kinase), which initiates the local translation of mRNAs required to maintain synaptic growth and long-term facilitation past 24 hours. Some of the mRNAs at the terminals encode CPEB, a regulator of local protein synthesis. In the basal state CPEB is thought to exist in a largely inactive conformation as a soluble monomer that cannot bind to mRNAs. Through some as yet unspecified mechanism activated by serotonin and PI3 kinase, some copies of CPEB convert to an active conformation that forms aggregates. The aggregates function like prions in that they are able to recruit monomers to join the aggregate, thereby activating the monomers. The CPEB aggregates bind the cytoplasmic polyadenylation element (CPE) site of mRNAs. This binding recruits the poly(A) polymerase machinery and allows poly(A) tails of adenine nucleotides (A) to be added to dormant mRNAs. The polyadenylated mRNAs can now be recognized by ribosomes, allowing the translation of these mRNAs to several proteins. For example, in addition to CPEB, this leads to the local synthesis of N-actin and tubulin, which stabilize newly grown synaptic structures.

the flies to choose between two arms of a maze, where one arm contains the conditioned odor and the other arm contains an unpaired odor. Following training, a large fraction of wild-type flies avoids the arm with the conditioned odor. Several fly mutants have been identified that do not learn to avoid the conditioned odor. These learning-defective mutants have been

given imaginatively descriptive names such as *dumb*, *dunce*, *rutabaga*, *amnesiac*, and *PKA-R1*. Of great interest, all of these mutants have defects in the cAMP cascade.

Olfactory fear conditioning depends on a region of the fly brain called the mushroom bodies. Neurons of the mushroom bodies, called Kenyon cells, receive olfactory input from the antennal lobes, structures similar to the olfactory lobes of the mammalian brain. The Kenyon cells also receive input from neurons that release dopamine in response to aversive stimuli, such as a foot shock. The dopamine binds to a metabotropic receptor (encoded by the *dumb* gene) that activates a stimulatory G protein and a specific type of Ca²⁺/calmodulin-dependent adenylyl cyclase (encoded by the *rutabaga* gene), similar to the cyclase involved in classical conditioning in *Aplysia*. The convergent action of dopamine released by the unconditioned stimulus (foot shock) and a rise in intracellular Ca²⁺ triggered by olfactory input leads to the synergistic activation of adenylyl cyclase, producing a large increase in cAMP.

Recent experiments have demonstrated that flies can be classically conditioned when an odorant is paired with direct stimulation of the dopaminergic neurons, bypassing the foot shock. In these experiments the mammalian P2X receptor (an ATP-gated cation channel), is expressed as a transgene (see Box 3-3) in the dopaminergic neurons. The flies are then injected with a caged derivative of ATP. As a result the dopamine neurons can be excited to fire action potentials by shining light on the flies to release ATP from its cage and activate the P2X receptors. When the dopamine neurons are activated in the presence of an odor, the flies undergo fear conditioning; they learn to avoid the odor. Thus the unconditioned stimulus activates a modulatory signal mediated by dopamine that conveys aversive reinforcement, much as serotonin acts as an aversive reinforcement signal for learned fear in *Aplysia*.

A reverse genetic approach has also been used to explore memory formation in *Drosophila*. In these experiments various transgenes are placed under the control of a promoter that is heat-sensitive. The heat sensitivity permits the gene to be turned on at will. This was done in mature animals to minimize any potential effect on the development of the brain. When the catalytic subunit of PKA was blocked by transient expression of an inhibitory transgene, flies were unable to form short-term memory, indicating the importance of the cAMP signal transduction pathway for associative learning and short-term memory in *Drosophila*.

Long-term memory in *Drosophila* requires new protein synthesis just as in *Aplysia* and other animals. Like *Aplysia*, *Drosophila* expresses a CREB activator gene. Knockout of this gene selectively blocks long-term memory without interfering with short-term memory. Conversely, when the gene is overexpressed a training procedure that ordinarily produces only short-term memory produces long-term memory.

As in *Aplysia*, certain forms of long-term memory in *Drosophila* also involve CPEB and may depend on

prion-like activity in this protein. Male flies learn to suppress their courtship behavior as a result of exposure to unreceptive females. When the N-terminal domain of CPEB is deleted genetically, there is a loss of long-term courtship memory. This N-terminal domain is rich in glutamine residues and corresponds to the glutamine rich prion-like domain of CPEB in *Aplysia*. Thus several molecular mechanisms involved in implicit memory are conserved from *Aplysia* to flies, and, as we will see next, this conservation extends to mammals.

Memory for Learned Fear in Mammals Involves the Amygdala

Innate fear, the ability to recognize and respond to danger, is necessary for survival. Not only snails and flies but all animals as well as humans need to distinguish predators from prey and hostile environments from safe ones. Because innate fear has been conserved throughout the evolution of species, one can readily discern and study fear in a variety of experimental animals.

At the beginning of the 20th century both Pavlov and Freud independently discovered that fear can also be learned. A previously neutral stimulus, such as a tone, can become associated with a fearful stimulus, such as a painful shock, so that the tone leads to conditioned fear, a form of what Freud called "signal anxiety." Both Freud and Pavlov also appreciated that learned fear—anticipatory defensive responses to danger signals—is biologically adaptive and therefore also conserved in evolution. Learned fear prepares the individual for fight or flight if there is even the suggestion of external danger.

From the work of Joseph LeDoux, Michael Davis, and Michael Fanselow we now have a good understanding of the neural circuits for both instinctive and learned fear in mammals. In particular, we know that both are centered on the amygdala, which participates in the detection and evaluation of a broad range of significant and potentially dangerous environmental stimuli (see Chapter 48). The amygdala receives information about unconscious fear responses (emotional state) directly and information about the cognitive processing of fear (feelings) indirectly by means of connections from the cingulate cortex.

In addition to its innate ability to respond to routine, natural threats, the amygdala-based defense system is also able to learn quickly about new dangers. It can associate a new neutral (conditioned) stimulus with a known threatening (unconditioned) stimulus on a single paired exposure and this learned fear can be remembered throughout life. The input nucleus of the amygdala, the lateral nucleus, is the site of convergence for the signals

from the unconditioned stimulus (such as a shock) and the conditioned stimulus (such as a tone). Both signals are carried by a rapid direct pathway that goes directly from the thalamus to the amygdala and a slower indirect pathway that goes from the thalamus to the cortex and from there to the amygdala. These parallel pathways are important for conditioning of fear (Figure 66–12).

Long-term memory for learned fear in mammals requires CREB, as it does in *Aplysia* and *Drosophila*. In fact, in studies of the amygdala, Alcino Silva and his colleagues have found that neurons in the amygdala are recruited for long-term memory based on their basal levels of CREB expression. Neurons with large amounts of the CREB switch, required for long-term memory, are selectively recruited in fear learning. Indeed, the relative activity of CREB at the time of learning determines whether a neuron is recruited. Conversely, if those neurons with a large amount of CREB are selectively ablated after learning, the memory of fear is blocked.

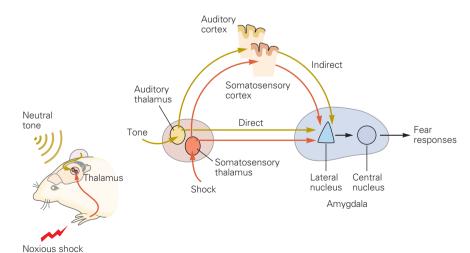

Pavlovian classical conditioning modifies the strength of synaptic transmission in the amygdala. In response to a tone, an extracellular electrophysiological signal proportional to the excitatory synaptic response is recorded in the lateral nucleus. Following pairing of the tone with a shock, the electrophysiological response is enhanced because of an increase in synaptic transmission (Figure 66–13).

What causes the enhanced synaptic response of learned fear? This question has been addressed by examining synaptic transmission in isolated brain slices containing the input pathways and nuclei of the amygdala. High-frequency tetanic stimulation of either the direct or indirect pathways induces a long-lasting increase in the synaptic response to these inputs (Figure 66–14). This change is a form of homosynaptic plasticity called *long-term potentiation* (LTP), which we examine in detail in Chapter 67 in connection with explicit memory and the hippocampus, where this mechanism was first identified.

Long-term potentiation in the lateral nucleus of the amygdala is triggered by Ca²⁺ influx into the postsynaptic neurons in response to strong synaptic activity. The Ca²⁺ entry is mediated by the opening of both NMDA-type glutamate receptors and L-type voltagegated Ca²⁺ channels in the postsynaptic cell. Calcium influx triggers a biochemical cascade that enhances synaptic transmission through both the insertion of additional AMPA-type glutamate receptors in the postsynaptic membrane and an increase in transmitter release from the presynaptic terminals. The persistence of the memory for learned fear and the synaptic changes also require both cAMP-dependent protein kinase and MAPK, which activate the transcription factor CREB to initiate gene expression, much like learned fear in Aplysia and Drosophila.

Are these experimentally induced activity-dependent synaptic changes important for the induction of learned fear or are they only corollary or parallel phenomena? Two types of genetic experiments support the idea that LTP provides a cellular mechanism for memory storage of learned fear. In one experiment genetic disruption of the GluN2B (NR2B) subunit of the NMDA receptor was found to interfere both with fear conditioning and

Figure 66-12 The neural pathways recruited during learned fear. The signal for the conditioned stimulus, here a neutral tone, is carried directly from the auditory thalamus to the lateral nucleus of the amygdala and by an indirect pathway via the auditory cortex. Similarly the signal for the unconditioned stimulus, here a shock, is conveyed through nociceptive pathways directly from the somatosensory part of the thalamus to the lateral nucleus and by an indirect pathway via the somatosensory cortex. The lateral nucleus in turn projects to the central nucleus, the output nucleus of the amygdala, which activates neural circuits that increase heart rate, produce other autonomic changes, and elicit defensive behaviors that constitute the fear state. (Reproduced, with permission, from Kandel 2006.)

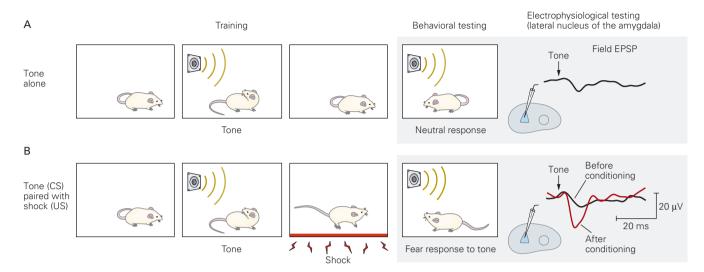

Figure 66–13 Learned fear produces parallel and correlated behavioral and electrophysiological changes.

A. An animal ordinarily ignores a neutral tone. The tone produces a small synaptic response in the amygdala recorded by an extracellular field electrode. This field EPSP is generated by the small voltage drop between the recording electrode in the amygdala and a second electrode on the exterior of the brain as excitatory synaptic current enters the dendrites of a large population of amygdala neurons.

B. When the tone is presented immediately before a foot shock (US), the animal learns to associate the tone (CS) with the shock. Now the tone alone will elicit what the shock previously elicited. Thus the tone causes the mouse to freeze, an instinctive fear response. After fear conditioning the electrophysiological response in the lateral nucleus of the amygdala to the tone is greater than the response prior to conditioning. (Reproduced, with permission, from Rogan et al. 2005.)

the induction of LTP in pathways that transmit the conditioned stimulus (tone) signal to the lateral amygdala. Moreover, this mutation affected only learned fear; it did not affect instinctive fear responses or routine synaptic transmission. Conversely, overexpression of the GluN2B subunit facilitated fear learning. Similarly, disruption of CREB signaling, a step downstream from Ca²⁺ influx, interfered with fear conditioning whereas enhancement of CREB activity facilitated learning.

Convincing evidence that LTP is important for learned fear comes from the finding that the size of the LTP elicited by electrical stimulation in slices of the amygdala isolated from animals previously trained for fear is reduced compared to the size of LTP in slices from animals that did not undergo prior fear training. This result is taken as evidence that fear learning recruits LTP: Because there is an upper limit to the amount by which synapses can be potentiated, the LTP induced by fear conditioning precludes further LTP in response to electrical stimulation. These results also suggest that artificially induced LTP and fear-induced LTP are related and are mutually exclusive.

A second line of experiments suggests that memory for a single emotional event requires the induction of LTP, and that a significant fraction of the total population of pyramidal cells in the lateral nucleus must express LTP to generate fear memory. In these experiments pyramidal neurons in the lateral nucleus were infected with a genetically engineered virus that did not damage the neurons but caused them to express AMPA receptors tagged with a fluorescent label. Fear conditioning led to an increase in insertion of the tagged AMPA receptors into the cell membrane, similar to what is seen during experimentally induced LTP in brain slices. When a different virus was used to express a C-terminal portion of the AMPA receptor that competes with and prevents the insertion of endogenous AMPA receptors, memory for learned fear was substantially reduced, even though the virus infected only 10% to 20% of the neurons in the lateral nucleus.

Habit Learning and Memory Require the Striatum

Habits are routines that are acquired gradually by repetition and are the result of a distinct form of implicit learning. A habit is a stimulus-response association, a behavior that is triggered simply by particular stimuli rather than by desire for (or fear of) some outcome.

In his classic book *The Principles of Psychology,* the great American psychologist William James characterized habit as the driving force of our daily operations—we are creatures of habit. As with all forms of implicit learning, habits are expressed in action alone, without conscious control, and not in verbal reports.

Many habits are learned early and retained throughout life. We learn to navigate through the world

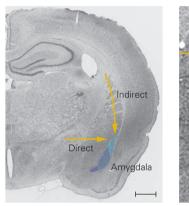

without conscious thought. Learned motor skills allow us to avoid objects in our path or to avoid bumping into people in a crowd. We learn through imitation, trial and error, practice and experience to dry ourselves and comb our hair after a shower, put on our clothes and even drive to work, all in a sequence that requires minimal attention. Much as proposed by Pavlov and the American psychologist Edward Thorndike, we can

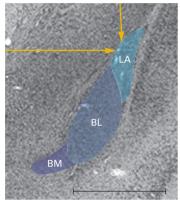

Figure 66–14 Long-term synaptic change in the amygdala may mediate fear conditioning.

A. A coronal brain slice from a mouse shows the position of the amygdala. The enlargement shows three key input nuclei of the amygdala—the lateral (LA), basolateral (BL), and basomedial (BM) nuclei—which together form the basolateral complex. These nuclei project to the central nucleus, which projects to the hypothalamus and brain stem. (Adapted, with permission, from Maren 1999.)

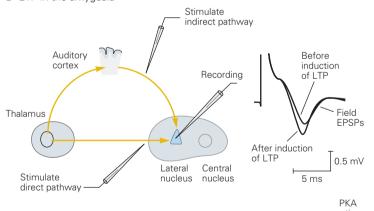

B. High-frequency tetanic stimulation of the direct or indirect pathway to the lateral nucleus initiates longterm potentiation (LTP). The drawing shows the position of the extracellular voltage recording electrode in the lateral nucleus, and the positions of two stimulating electrodes used to activate either the direct pathway (from the thalamus) or the indirect pathway (via the auditory cortex). The plot shows the amplitude of the extracellular field EPSP in response to stimulation of the indirect cortical pathway during the time course of the experiment. When a pathway is stimulated at a low frequency (once every 30 seconds), the field EPSP is stable. However, when five trains of high-frequency tetanic stimulation are applied (asterisks) the response is enhanced for a period of hours. The facilitation depends on PKA and is compromised when the PKA inhibitor KT5720 is applied (the bar shows period of drug application). Field EPSPs before and after induction of LTP are also shown. (Adapted, with permission, from Huang and Kandel 1998; Huang, Martin, and Kandel 2000.)

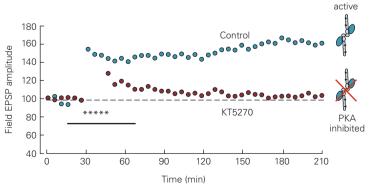

A Basolateral complex of the amygdala

B LTP in the amygdala

build up complex behaviors by combining simpler behaviors learned through repeated stimulus-response conditioning.

Many forms of habit learning depend on the four nuclei of the basal ganglia: the striatum, globus pallidus, substantia nigra, and subthalamic nucleus (see Chapter 43). The striatum, the input nucleus, has three subdivisions (at least in humans and other primates): the caudate nucleus, the putamen, and the ventral striatum. The caudate nucleus is involved in certain forms of procedural learning, including stimulus-response associations and some forms of skill learning. It and the ventral striatum malfunction in a variety of diseases in which habit learning is disordered, including obsessive-compulsive disorder and addiction.

Striatum-based implicit memory differs from hippocampus-based explicit memory in interesting ways. Mark Packard and his colleagues demonstrated fundamental differences in the neural structure underlying the two types of memory. They tested both types of memory using the same eight-arm maze (Figure 66–15). Explicit memory was tested with a "win-shift" foraging task. A rat was placed in the maze daily and removed after it had collected food from every arm, and this was repeated over several consecutive days. The rat's task was to minimize wasted effort by remembering where it had already found food (a win); to avoid revisiting those arms the rat had to shift its focus to the

unvisited arms. In performing this task the animal has to acquire and use information about single events. It must remember the specific locations it has visited on a given day. This type of learning requires the hippocampus and is impaired by its lesion. Damage to the caudate nucleus has no effect on this behavior.

The same maze was then used to teach the rat a "win-stay" strategy, an example of implicit learning. With this task the animal needs to learn to visit four of the eight arms of the maze that are identified by a light at the entrance. Only these four arms contained a food reward. Over two weeks of training the animals learned to revisit only the arms that were lit. The win-stay task, in contrast to the win-shift task, is disrupted by damage to the caudate nucleus but not by damage to the hippocampus. The two tasks are superficially similar, but the win-stay task requires the animal to learn about regularities that are constant from day to day (lit arms always contain food) rather than to remember specific events on a given day (which unmarked arms it has already visited).

Examination of such striatum-dependent learning in mice has begun to shed light on the molecular mechanisms underlying habit learning. As is the case with many forms of implicit memory, striatum-based habit memory also requires CREB. Animals with selective impairment of CREB function in the striatum show impaired striatum-dependent learning.

A Explicit learning

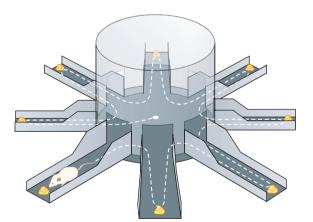

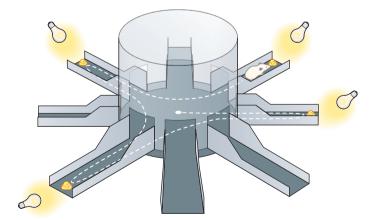

Figure 66–15 An eight-arm maze is used to demonstrate the difference between explicit and implicit learning. (Adapted, with permission, from Packard, Hirsh, and White 1989; Squire and Kandel 2008.)

A. In an explicit learning task a rat finds that food is available at the end of each arm. Initially a rat enters arms at random; with

B Implicit learning

practice the animal will learn to find all of the eight morsels by entering each arm only once (by following a path similar to the one shown by the dashed line).

B. In an implicit learning task food is available only in four arms that are illuminated. The animal learns to visit each of these arms by associating the light with the food.

In the striatal learning system one likely locus of synaptic plasticity is the excitatory projection from the cortex to the striatum. This pathway undergoes a form of LTP that is mediated by NMDA receptors, much like that at the synaptic sites in the amygdala involved in learned fear. Like LTP in the amygdala, the persistence of LTP at corticostriatal synapses also requires CREB and is impaired in mice when CREB function in the striatum is selectively inhibited. The parallel impairment of synaptic plasticity and learning in the striatum is similar to what has been seen in *Drosophila* and *Aplysia* as well as in the mammalian amygdala, and supports the view that transcriptional-dependent alterations in synaptic strength provide a general mechanism of implicit memory.

Learning-Induced Changes in the Structure of the Brain Contribute to the Biological Basis of Individuality

To what extent do the anatomical alterations in synapses required for long-term memory storage alter the large-scale functional architecture of the mature brain? The answer is well illustrated by the fact that the maps of the body surface in the primary somatic sensory cortex differ among individuals in a manner that reflects the use of specific sensory pathways. This remarkable finding results from the expansion or retraction of the connections of sensory pathways in the cortex according to the specific experience of the individual (see Chapter 17).

The reorganization of afferent inputs as a result of behavior is also evident at lower levels in the brain, specifically at the level of the dorsal column nuclei, which contain the first synapses of the somatic sensory system. Therefore organizational changes probably occur throughout the somatic afferent pathway.

The process by which experience alters the somatosensory maps in the cortex is illustrated in an experiment in which adult monkeys were trained to use their middle three fingers at the expense of other fingers to obtain food. After several thousand trials of this behavior, the area of cortex devoted to the middle fingers expanded greatly (see Figure 66–16A). Thus practice may expand synaptic connections by strengthening the effectiveness of existing connections.

The normal development of the afferent input to cortical neurons in the somatosensory system may depend on different levels of activity in neighboring afferent axons. When the skin surfaces of two adjacent fingers in monkeys were surgically connected so that the connected fingers were always used together, thus ensuring that their afferent somatosensory axons were

normally coactivated, the normally sharp discontinuity between the zones in the somatosensory cortex that receive inputs from these digits was abolished. Thus normal development of the boundaries of representation of adjacent fingers in the cortex may be guided not only genetically but also through experience. Fine tuning of cortical connections may depend on associative mechanisms such as LTP, similar to the role of cooperative activity in shaping the development of ocular dominance columns in the visual system (see Chapter 56).

This plasticity is evident in humans as well. Thomas Elbert explored the hand representation in the motor cortex of string instrument players. These musicians use their left hand for fingering the strings, manipulating the fingers in a highly individuated way. By contrast, the right hand, used for bowing, is used almost like a fist. The representation of the right hand in the cortex of string instrument players is the same as that of nonmusicians. But the representation of the left hand is greater than in nonmusicians and substantially more prominent in players who started to play their instrument prior to age 13 years (Figure 66–16B).

Because each of us is brought up in a somewhat different environment, experiencing different combinations of stimuli and developing motor skills in different ways, each individual's brain is uniquely modified. This distinctive modification of brain architecture, along with a unique genetic makeup, constitutes a biological basis for individuality.

An Overall View

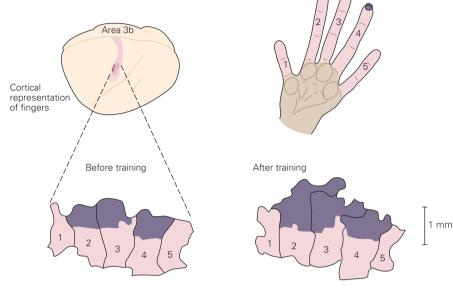

A striking feature of implicit or procedural memory storage is that the recall of this memory is accomplished without recourse to conscious thought. Many aspects of personality, much of what we do in our daily life, is guided by implicit memory. These principles are consistent with a central tenet of psychoanalytic theory, the idea that we are unaware of much of our mental life. A great deal of what we experience—what we perceive, think, fantasize—cannot be directly accessed by conscious thought. Nor can we explain what often motivates our actions. The idea of unconscious mental processes not only is important in its own right but it is critical in the approach to neuroscientific studies of implicit memory storage and the resulting consequences for our individuality.

As we learned in Chapter 65, Brenda Milner made the remarkable discovery in 1954 that the medial temporal lobe, especially the hippocampus, mediates storage of what we now call explicit memory, the memory

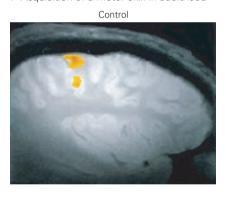

Figure 66–16 Training expands existing representation in the cortex of inputs from the fingers.

- A. A monkey was trained for 1 hour per day to perform a task that required repeated use of the tips of fingers 2, 3, and occasionally 4. After training the portion of area 3b of the somatosensory cortex representing the tips of the stimulated fingers (dark color) is substantially greater than normal (measured 3 months prior to training). (Adapted, with permission, from Jenkins et al. 1990.)
- B. 1. A human subject trained to do a rapid sequence of finger movements will improve in accuracy and speed after 3 weeks of daily training (10-20 min each day). Functional magnetic resonance imaging scans of the primary motor cortex (based on local blood oxygenation level-dependent signals) show that after 3 weeks of training the region activated in trained subjects (orange region) is larger than the region activated in control subjects who performed unlearned finger movements in the same hand. The change in cortical representation in trained subjects persisted for several months. (Reproduced, with permission, from Karni et al. 1998.)
- 2. The size of the cortical representation of the fifth finger of the left hand is greater in string players than in nonmusicians. The graph plots the dipole strength obtained from magnetoencephalography, a measure of neural activity. The increase is most pronounced in musicians that began musical training before age 13. (Reproduced, with permission, from Elbert et al. 1995.)

for people, objects, and places that is consciously recalled. In 1962 she made the further discovery that even though the patient H.M. had no conscious recall of new experiences with people, places, and objects, he was nonetheless fully capable of learning new perceptual and motor skills. This learning is stored in what we now call implicit memory, which is "recalled" only in performance and not typically reached through conscious recall.

Using the two memory systems together is the rule rather than the exception. The two systems overlap and are commonly used together in many learning experiences. Indeed, constant repetition often can transform explicit learning into implicit learning. For example, learning to drive an automobile at first involves conscious recollection; many aspects of driving eventually become an automatic and nonconscious motor activity.

Implicit memory itself comprises several processes that involve different brain systems. Acquisition of emotional states involves the amygdala; formation of new motor (and perhaps cognitive) habits requires the neostriatum; learning new motor behavior depends on the cerebellum; and simple reflex learning occurs directly in sensory and motor pathways. In different situations and learning experiences implicit memory formation depends on different combinations of these components of the nervous system. These implicit memory systems also work in parallel with the explicit memory system of the hippocampus so that with extensive experience explicit memory can essentially be carried forward by implicit memory systems.

In implicit memory, then, we have a biological manifestation of one component of unconscious mental life. How does this biologically delineated unconscious process relate to Freud's concept of the unconscious? In his later writings Freud used the term "unconscious" in different ways. Sometimes he used it in a strict way to refer to the *repressed* or *dynamic unconscious*. In this dynamic unconscious information about conflict and drive is prevented from reaching consciousness by powerful defensive mechanisms such as repression. This dynamic unconscious is what the classical psychoanalytic literature refers to simply as the unconscious.

At the same time, Freud proposed another component of unconscious activity, one concerned with habits and with perceptual and motor skills. This component fits our current understanding of implicit memory. According to Freud, an individual is not aware of most of the mental processes underlying our habits and as a result underlying these aspects of our personality. This idea is consistent with current neurological thinking that much of mental life is unconscious.

As these arguments make clear, the empirical study of unconscious psychic processes was severely limited for many years by the lack of suitable experimental methods. Today, however, biology has a wide range of empirical methods that are providing cellular and molecular insights that are expanding our understanding of a very wide range of mental activity.

Are There Molecular Building Blocks for Learning?

An Overall View

EXPLICIT MEMORY—THE CONSCIOUS recall of information about people, places, and objects—is what people commonly think of as memory. Sometimes called *declarative memory*, it binds our mental life together by allowing us to recall at will what we ate for breakfast, where we ate it, and with whom. It allows us to join what we did today with what we did yesterday or the week or month before that.

The two structures in the mammalian brain that are critical for encoding and storing explicit memories are the prefrontal cortex and the hippocampus. The prefrontal cortex mediates working memory (see Chapter 65). Information stored in working memory can be actively maintained for very short periods and then rapidly forgotten, such as a telephone number that is remembered only until it is dialed, or it can be stored elsewhere in the brain as long-term memory. The hippocampus stores declarative information in a more stable form for periods ranging from days to weeks to years, up to a lifetime. The ultimate storage site for all declarative memories is thought to be in the cerebral cortex. In this chapter we focus on the cellular and molecular mechanisms underlying working memory and long-term storage of explicit memories.

Working Memory Depends on Persistent Neural Activity in the Prefrontal Cortex

In vivo electrophysiological recordings from neurons in the prefrontal cortex of nonhuman primates have provided insights into the neural basis of working memory. Neuronal activity is measured while the animal is engaged in a delayed match-to-sample working memory task. In such tasks the animal is initially shown an image (the sample) and must retain the image in working memory for seconds to minutes after the initial image is extinguished (the delay period). The monkeys are then shown a test image and must press a lever to indicate whether the test image matches the sample image.

Neurons in the prefrontal cortex fire persistently during the delay period, presumably contributing to the neural representation of the image in working memory. Two major mechanisms may contribute to this persistent neural activity: the intrinsic properties of neuronal membranes and recurrent synaptic connectivity.

Intrinsic Membrane Properties Can Generate Persistent Activity

In some cortical neurons a brief electrical stimulation can lead to persistent firing that lasts for seconds or even minutes after the end of the stimulus (Figure 67–1A). Moreover, the rate of firing can be a graded function of the intensity of the stimulation. This persistent firing is not affected by blockers of fast excitatory and inhibitory synaptic transmission, indicating that it depends on the intrinsic membrane properties of the neuron.

The intrinsic mechanism underlying persistent firing has been best characterized in neurons in the deep layers of the entorhinal cortex. Normally a brief depolarizing current pulse elicits a transient burst of action potentials in these neurons. However, when the entorhinal neurons are exposed to acetylcholine, which activates G-protein coupled muscarinic receptors, a brief depolarizing current elicits a prolonged train of action potentials that persists for tens of seconds, far longer than the current stimulus.

This maintained firing depends on the opening of a type of channel termed the Ca^{2+} -activated non-selective (CAN) cation channel. The opening of these channels requires two simultaneous events. First, the muscarinic receptor signaling cascade must be stimulated by extracellular acetylcholine; second, there must be an increase in intracellular Ca^{2+} , normally generated by the opening of voltage-gated Ca^{2+} channels during the firing of a brief burst of action potentials. Ca^{2+} then opens the CAN channel by binding to a site on the channel's cytoplasmic surface. As the cytoplasmic Ca^{2+} level remains elevated for some time after the burst of action potentials, the inward current through the CAN channels leads to a prolonged afterdepolarization following the burst of action potentials.

If the initial stimulation period is sufficiently intense, the Ca²⁺ influx will activate sufficient current through the CAN channels so that the afterdepolarization will trigger a second round of spikes. This in turn leads to more Ca²⁺ influx, which activates more CAN channels, leading to a larger afterdepolarization that can maintain firing that far outlasts the initial stimulus. Thus these CAN channels contribute to persistent firing by participating in a positive feedback loop with voltage-gated Ca²⁺ channels. Recent studies suggest that this mechanism of persistent firing also is observed in prefrontal cortex neurons.

Network Connections Can Sustain Activity

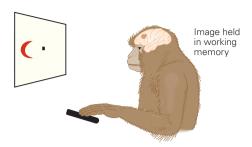

The second type of mechanism for sustained firing depends on recurrent synaptic connections within neural circuits. In the simplest case activity is maintained by recurrent excitatory connections within the active population of neurons. A network can comprise either long-range connections between distinct regions of the brain or local circuits (Figure 67–1B). The firing maintained through such chains is referred to as *reverberatory* activity.

Another circuit that can sustain activity depends on reciprocal inhibitory synapses between two populations of neurons (Figure 67–1B). Neurons in both populations fire spontaneously at a basal level that is normally held in check by the reciprocal inhibitory synapses. However, a brief excitatory input to one population of neurons will transiently enhance their firing rate, which leads to an increase in their inhibitory output onto the second population. As a result, the firing rate of the second population decreases. This decreases the inhibitory input onto the first population of neurons, further enhancing their rate of firing.

This mechanism of positive feedback, termed disinhibition, can lead to firing of the first population of neurons that outlasts the initial stimulus. A network of reciprocal inhibitory connections between distinct populations of neurons contributes to the sustained firing of oculomotor neurons such as those of the goldfish, which are responsible for remembering eye position. It is likely that persistent activity during working memory involves a combination of network and intrinsic mechanisms.

Working Memory Depends on the Modulatory Transmitter Dopamine

Although the relative importance of intrinsic activity versus network activity in working memory remains uncertain, it is clear that the efficiency of working memory and persistent activity in prefrontal cortex neurons depends on the state of activation of the D_1 type of dopamine receptors. These receptors are coupled to

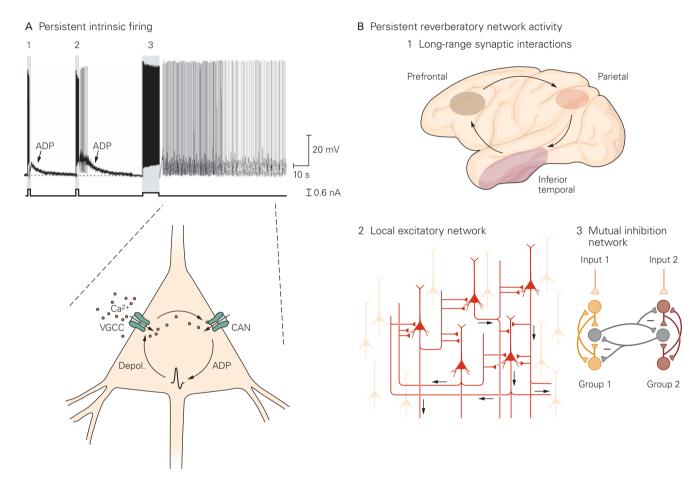

Figure 67–1 Mechanisms of persistent neuronal activity that may contribute to working memory. When a monkey performs a working memory task neurons in prefrontal cortex fire persistently during the delay period of the task.

A. Intrinsic mechanisms of graded persistent activity. A brief depolarizing stimulus to a pyramidal neuron in the entorhinal cortex elicits a short burst of action potentials followed by an afterdepolarization (ADP) (1). A slightly longer stimulus elicits a longer burst of spikes followed by a larger afterdepolarization (2). When the stimulus is further lengthened, the afterdepolarization is sufficient to trigger additional action potentials, leading to persistent firing for tens of seconds (3). The diagram illustrates a potential mechanism for the persistent firing. The influx of Ca²⁺ through voltage-gated Ca²⁺ channels (VGCC) during an action potential opens Ca²⁺-activated nonselective cation (CAN) channels. The resulting inward current through the CAN channels produces an afterdepolarization that can lead to action potentials. The action potentials further activate VGCCs, perpetuating the cycle. The recordings were obtained in the presence of

carbachol, which activates muscarinic acetylcholine (ACh) receptors and a downstream signaling cascade that enables the opening of CAN channels when intracellular Ca²⁺ is also elevated. (Reproduced, with permission, from Egorov et al. 2002.)

B. Recurrent networks of synaptically coupled neurons can lead to persistent reverberatory activity. 1. Some network interactions occur between two widely separated populations of excitatory neurons in distinct brain regions. 2. Other excitatory networks are local, illustrated here by reciprocally connected neighboring pyramidal neurons in neocortex. 3. Persistent activity can be generated through mutual inhibition. This example consists of two populations of neurons, groups 1 and 2. Within each population the neurons are reciprocally connected by excitatory synapses. However, each population mutually inhibits the other. In this manner an excitatory input to group 1 leads to the silencing of group 2. The loss of inhibitory input from group 2 (a process termed *disinhibition*) in turn enhances the firing of group 1 (B1 and B2 reproduced, with permission, from Wang 2001; B3 reproduced, with permission, from Aksay et al. 2007.)

the G protein G_s and the production of cyclic adenosine monophosphate (cAMP).

Patricia Goldman-Rakic and colleagues have found that there is an inverted U-shaped relation between the extent of D_1 receptor activation and working memory: Working memory is most efficacious at intermediate levels of D_1 receptor activation. Defects in the dopaminergic regulation of working memory in prefrontal cortex are thought to contribute to the cognitive deficits associated with schizophrenia.

Explicit Memory in Mammals Involves Different Forms of Long-Term Potentiation in the Hippocampus

What neural mechanisms are responsible for long-term explicit memory mediated by the hippocampus and its associated structures in the medial temporal lobe of the mammalian brain? Unlike working memory, long-term storage of information by the hippocampus is not thought to depend on persistent neural firing but rather to involve long-lasting changes in the strength of synaptic connections.

The hippocampus receives multimodal sensory and spatial information from the nearby entorhinal cortex. The major output of the hippocampus is through the pyramidal neurons in the CA1 region, which project back to the entorhinal cortex and to the subiculum, another medial temporal lobe structure. The critical importance of CA1 neurons in learning and memory is seen in the profound memory loss exhibited by patients with lesions in this region, which has been complemented by numerous studies in animal models. Information from the entorhinal cortex reaches CA1 neurons along two excitatory pathways, one direct pathway and one indirect. Together these inputs are termed the *perforant pathways*.

The direct pathway has its origins in neurons of layer III of the entorhinal cortex. The axons of these neurons form synapses on the very distal apical dendrites of CA1 neurons (such perforant projections are also called the temporoammonic pathway). In the indirect pathway information from neurons of layer II of the entorhinal cortex reaches CA1 neurons through the trisynaptic pathway. In the initial leg of this pathway the axons of layer II neurons project through the perforant pathway to the granule cells of the dentate gyrus (an area considered part of the hippocampus). The granule cell axons project in the mossy fiber pathway to excite the pyramidal cells in the CA3 region of the hippocampus. Finally, the CA3 axons project through the Schaffer collateral pathway to make excitatory synapses on more

proximal regions of CA1 pyramidal cell dendrites (Figure 67–2).

The fact that CA1 pyramidal neurons receive cortical information through two pathways has led to the view that CA1 neurons compare information in the indirect circuit with sensory input from the direct pathway. Lesion studies indicate that both direct and indirect inputs to CA1 may be necessary for normal learning and memory. Lesions of the indirect Schaffer collateral pathway limit the ability of mice to perform a complex spatial learning and memory task, although some form of spatial learning remains intact. Lesions of the direct pathway to CA1 do not appear to alter initial formation of memory, but inhibit the ability of an animal to store those initial memories as long-term memory, a process termed consolidation. Genetic inactivation of the direct path also interferes with episodic memory, in which an animal must learn about the temporal relation between two or more events.

In 1973 Timothy Bliss and Terje Lomø discovered that the initial stage of the trisynaptic pathway—the perforant pathway from layer II of the entorhinal cortex to the dentate granule neurons—is remarkably sensitive to previous activity. A brief high-frequency train of stimuli (a tetanus) gives rise to long-term potentiation (LTP), a long-lasting increase in the amplitude of the excitatory postsynaptic potentials (EPSPs) in the dentate granule neurons. (In Chapter 66 we saw how a similar form of synaptic potentiation at synapses in the amygdala contributes to fear conditioning.) Subsequent studies showed that brief high-frequency trains of stimulation can induce forms of LTP at all three synapses of the trisynaptic pathway as well as at the direct perforant path synapses with CA1 neurons (Figure 67–3). Long-term potentiation can last for days or even weeks when induced in the intact animal using implanted electrodes. LTP can also be examined in slices of hippocampus and in cell culture, where it can last several hours.

Studies in these different pathways have shown that LTP is not a single form of synaptic plasticity. Rather it comprises a family of processes that strengthen synaptic transmission at different hippocampal synapses through distinct cellular and molecular mechanisms. Indeed, even at a single synapse different forms of LTP can be induced by different patterns of synaptic activity. However, these distinct processes also share many important similarities.

All forms of LTP are induced by synaptic activity in the pathway that is being potentiated—that is, LTP is homosynaptic. However, the various forms of LTP differ in the relative importance of different receptors and ion channels. In addition, different forms of

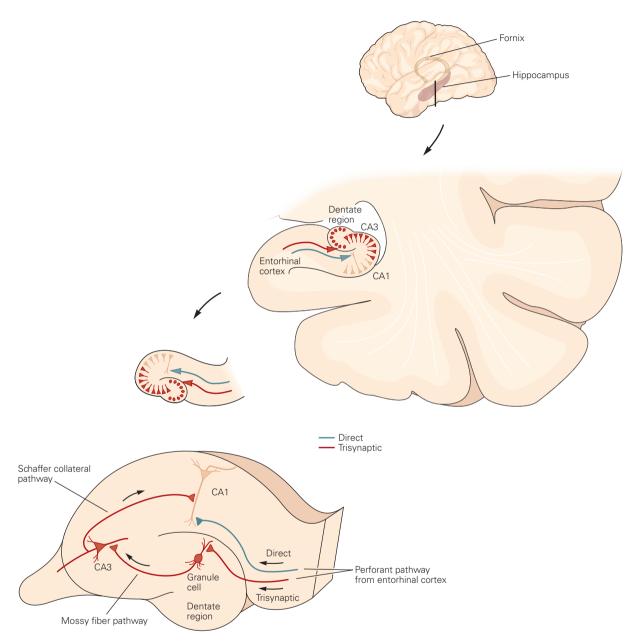

Figure 67–2 The hippocampal synaptic circuit is important for declarative memory. Information arrives in the hippocampus from entorhinal cortex through the *perforant pathways*, which provide both direct and indirect input to CA1 pyramidal neurons, the major output neurons of the hippocampus. (**Arrows** denote the direction of impulse flow.) In the indirect *trisynaptic pathway* neurons in layer II of entorhinal cortex send their axons through the perforant path to make excitatory synapses onto the granule cells of the dentate gyrus. The granule

cells project through the mossy fiber pathway and make excitatory synapses with the pyramidal cells in area CA3 of the hippocampus. The CA3 cells excite the pyramidal cells in CA1 by means of the Schaffer collateral pathway. In the *direct pathway* neurons in layer III of entorhinal cortex project through the perforant path to make excitatory synapses on the distal dendrites of CA1 pyramidal neurons without intervening synapses.

Mossy fiber pathway

Figure 67-3 Different neural mechanisms underlie longterm potentiation at each of the three synapses in the trisynaptic pathway in the hippocampus. Long-term potentiation (LTP) is present at synapses throughout the hippocampus but depends to differing degrees on activation of NMDA-type glutamate receptors.

A. Tetanic stimulation of the Schaffer collateral pathway (at arrow) induces LTP at the synapses between presynaptic terminals of CA3 pyramidal neurons and their postsynaptic CA1 pyramidal neurons. The graph plots the size of the extracellular field EPSP (fEPSP) expressed as a percent of the initial baseline fEPSP prior to induction of LTP. At these synapses LTP requires activation of the NMDA receptors in the CA1 neurons as it is completely blocked when the tetanus is delivered in the presence of the NMDA receptor antagonist APV. (Reproduced, with permission, from Morgan and Teyler 2001.)

- B. Tetanic stimulation of the direct pathway from entorhinal cortex to CA1 neurons generates LTP of the fEPSP that depends partially on activation of the NMDA receptors and partially on activation of L-type voltage-gated Ca2+ channels. It is therefore only partially blocked by APV. Addition of APV and nitrendipine. a dihydropyridine that blocks L-type channels, is needed to fully inhibit LTP. (Reproduced, with permission, from Remondes and Schuman 2003.)
- C. Tetanic stimulation of the mossy fiber pathway induces LTP at the synapses with the pyramidal cells in the CA3 region. In this experiment the excitatory postsynaptic current was measured under voltage-clamp conditions. This LTP does not require activation of the NMDA receptors and so is not blocked by APV. It does require activation of protein kinase A and so is blocked by the kinase inhibitor H-89. (Reproduced, with permission, from Zalutsky and Nicoll 1990.)

LTP may recruit different second-messenger signaling pathways either in the presynaptic cell, altering transmitter release, or in the postsynaptic cell, altering its sensitivity to the neurotransmitter glutamate.

The similarities and differences in the mechanisms of LTP at the Schaffer collateral, mossy fiber, and entorhinal inputs to CA1 can be seen by examining the role of the postsynaptic NMDA type of glutamate receptor in the induction of LTP in the three pathways. In all three pathways synaptic transmission is persistently enhanced in response to a brief tetanic stimulation. However, the contribution of the NMDA receptor to the induction of LTP differs in the three pathways.

At the Schaffer collateral synapses with CA1 pyramidal neurons, the induction of LTP in response to a brief 100 Hz stimulation is completely blocked when the tetanus is applied in the presence of the NMDA receptor antagonist 2-amino-5-phosphonovaleric acid, (AP5 or APV). However, APV only partially inhibits the induction of LTP at the direct entorhinal synapses with CA1 neurons and has no effect on LTP at the mossy fiber synapses with CA3 pyramidal neurons (Figure 67–3). In the next two sections we consider the mechanisms of LTP in more detail, first in the mossy fiber pathway and then in the Schaffer collateral pathway.

Long-Term Potentiation in the Mossy Fiber Pathway Is Nonassociative

Glutamate released at the mossy fiber synapses binds to both the NMDA and AMPA type of glutamate receptors in the postsynaptic membrane of the CA3 neurons. However, under most conditions the NMDA receptors have only a minor role in synaptic transmission in this pathway. Moreover, as noted above, blocking these receptors has no effect on LTP (Figure 67–3C). Rather, LTP in the mossy fiber pathway is triggered by the large Ca²⁺ influx into the presynaptic terminals during a tetanus. In the presynaptic cell the Ca²⁺ influx activates a calcium/calmodulin-dependent adenylyl cyclase complex, thereby increasing the production of cAMP and activating protein kinase A. This leads to an increase in the release of glutamate from the mossy fiber terminals, resulting in LTP. Activity in the postsynaptic cell is not required for this form of LTP. Thus, mossy fiber LTP is nonassociative.

The increase in transmitter release is thought to depend on the ability of protein kinase A to phosphorylate RIM1 α , a synaptic vesicle protein that interacts with several other presynaptic proteins important for exocytosis (see Chapter 12). Thus mossy fiber LTP is abolished in mice in which the gene for RIM1 α has been deleted through genetic engineering. The importance

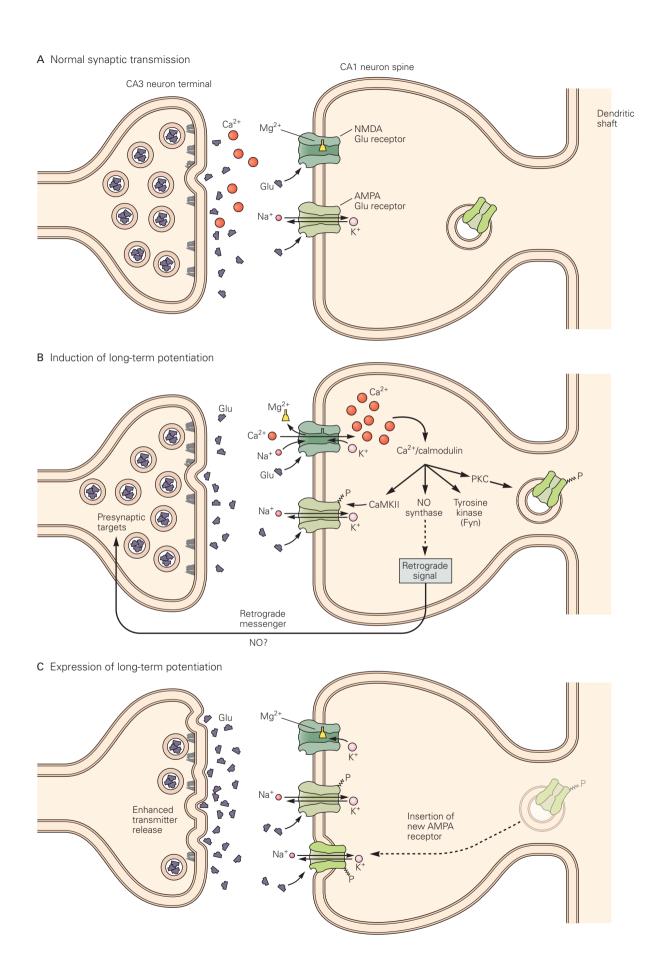

of presynaptic protein kinase A in mossy fiber LTP resembles aspects of the synaptic changes responsible for associative learning in the gill-withdrawal reflex of *Aplysia* and amygdala-based learned fear in rodents (see Chapter 66). Another similarity with the synaptic changes in *Aplysia* is that induction of mossy fiber LTP is under the control of a system of modulatory inputs. Just as the activation of adenylyl cyclase by serotonin is important for long-term facilitation in *Aplysia*, mossy fiber LTP is facilitated by the binding of norepinephrine to β -adrenergic receptors, enhancing the activation of adenylyl cyclase.

Long-Term Potentiation in the Schaffer Collateral Pathway Is Associative

Like the mossy fiber terminals in the CA3 region, glutamate released from the Schaffer collateral terminals activates both AMPA and NMDA receptors in the postsynaptic membrane of CA1 pyramidal neurons. However, unlike the mossy fiber system, LTP in the Schaffer collateral pathway requires activation of the NMDA receptors in the postsynaptic cell, which triggers a complex postsynaptic signaling cascade.

The opening of the NMDA receptors, unlike the AMPA receptors, requires that two events occur simultaneously. First, like any ionotropic receptor, glutamate must bind to the NMDA receptor to open the channel. However, when the membrane is at the resting potential or only modestly depolarized by a weak synaptic input, glutamate binding by itself is not sufficient for the NMDA receptors to conduct ions because the pore of the receptor-channel is blocked by extracellular Mg²⁺ (Figure 67–4A; see Chapter 10). For the receptor to function efficiently, the postsynaptic membrane must undergo a significant depolarization to expel the bound Mg²⁺ by electrostatic repulsion. In this manner the receptor acts as a coincidence detector: It is functional only when action potentials in the presynaptic neuron release glutamate that binds to the receptor and the membrane potential of the postsynaptic cell is sufficiently depolarized.

Because of the Mg²⁺ blockade of the NMDA receptors, at negative voltages near the resting potential EPSPs are largely generated by the opening of AMPA receptors. The burst of strong synaptic activity during induction of LTP opens a large number of AMPA receptors, generating an EPSP that is sufficient to trigger a postsynaptic action potential. The action potential generates a large depolarization that is able to expel Mg²⁺ from the pore of the NMDA receptor, permitting the receptor to conduct cations and contribute to the postsynaptic depolarization.

Why are the NMDA receptors required to induce LTP if the AMPA receptors are sufficient to produce a large postsynaptic depolarization? The answer lies in the fact that in addition to conducting monovalent Na⁺ and K⁺ ions, similar to the conductance properties of the AMPA receptors, the NMDA receptors also have a high permeability to Ca²⁺. Thus activation of these receptors leads to a significant increase in the intracellular Ca²⁺ concentration in the postsynaptic cell. The Ca²⁺ elevation is vital to the induction of LTP; injection of a chemical chelator of Ca²⁺ into the postsynaptic CA1 cell blocks the induction of LTP. The increase in Ca²⁺ activates several downstream signaling pathways, including calcium/calmodulin-dependent protein kinase II (CaMKII), protein kinase C (PKC), and tyrosine kinases. These signaling pathways lead to changes that both enhance the response of the postsynaptic cell to glutamate and increase the amount of glutamate released from the presynaptic Schaffer collateral terminals (Figure 67–4B).

Neuroscientists often find it useful to distinguish between the mechanisms underlying the *induction* of LTP (the biochemical reactions activated by the tetanic stimulation) and those responsible for the *expression* of LTP (the long-term changes that take place at the synapse responsible for enhanced synaptic transmission). The mechanisms for the induction of LTP at the CA3-CA1 synapse are postsynaptic. What are the mechanisms involved in the expression of LTP at this synapse? Is the enhancement caused by an increase in transmitter release, an increased postsynaptic response to a fixed amount of transmitter, or some combination of the two?

Recent studies suggest that the cellular mechanisms underlying the expression of LTP vary depending on the precise pattern of activity that induces LTP. In many cases LTP that is induced solely by Ca²⁺ influx

through NMDA receptors appears to be largely caused by an increase in the response of the postsynaptic membrane of the CA1 neuron to glutamate. But other patterns of stimulation elicit other forms of LTP at the same synapse and these also have presynaptic effects that enhance transmitter release.

One of the key pieces of evidence for a postsynaptic contribution to the expression of LTP at Schaffer collateral synapses comes from an examination of so-called "silent synapses" (Figure 67–5). In some recordings from pairs of hippocampal pyramidal neurons, stimulation of an action potential in one neuron fails to elicit a synaptic response in a second (postsynaptic) neuron when that neuron is at its resting potential (approximately –70 mV).

This result is not surprising as any given hippocampal presynaptic neuron is connected to only a small fraction of other neurons. However, what is surprising is that, in some neuronal pairs, when the second neuron is depolarized under voltage clamp to +30 mV, which removes the Mg²⁺ block from the NMDA receptors, stimulation of the presynaptic neuron elicits a large excitatory postsynaptic current (EPSC) in the postsynaptic neuron, mediated by the NMDA receptors. This result indicates that the two neurons were synaptically connected all along but the postsynaptic neuron contained only NMDA receptors at its synaptic contact with the presynaptic neuron. These connections are called silent synapses because they do not generate an EPSP at the normal resting potential of the cell as a result of the Mg²⁺ block of the NMDA receptors. Synapses from other presynaptic neurons on the same postsynaptic cell may have AMPA receptors in addition to NMDA receptors (nonsilent synapses).

The key finding from these experiments is seen following the induction of LTP. Pairs of neurons initially connected solely by silent synapses now often exhibit

Figure 67–4 (Opposite) A model for the induction of longterm potentiation at Schaffer collateral synapses.

A. During normal, low-frequency synaptic transmission glutamate released from the terminals of CA3 Schaffer collateral axons acts on both NMDA and AMPA receptors in the postsynaptic membrane of dendritic spines (the site of excitatory input) of CA1 neurons. Sodium and K⁺ flow through the AMPA receptors but not through the NMDA receptors because their pore is blocked by Mg²⁺ at negative membrane potentials.

B. During a high-frequency tetanus the large depolarization of the postsynaptic membrane (caused by strong activation of the AMPA receptors) relieves the Mg²⁺ blockade of the NMDA receptors, allowing Ca²⁺, Na⁺, and K⁺ to flow through these channels. The resulting increase of Ca²⁺ in the dendritic spine

triggers calcium-dependent kinases—calcium/calmodulin—dependent kinase (CaMKII) and protein kinase C (PKC)—as well as the tyrosine kinase Fyn, leading to induction of LTP.

C. Second-messenger cascades activated during induction of LTP have two main effects on synaptic transmission. Phosphorylation through activation of protein kinases, including PKC, enhances current through the AMPA receptors, in part by causing insertion of new receptors into the spine synapses. In addition, the postsynaptic cell releases (in ways that are still not understood) retrograde messengers that activate protein kinases in the presynaptic terminal to enhance subsequent transmitter release. One such retrograde messenger may be nitric oxide (NO), produced by the enzyme NO synthase (shown in part B).

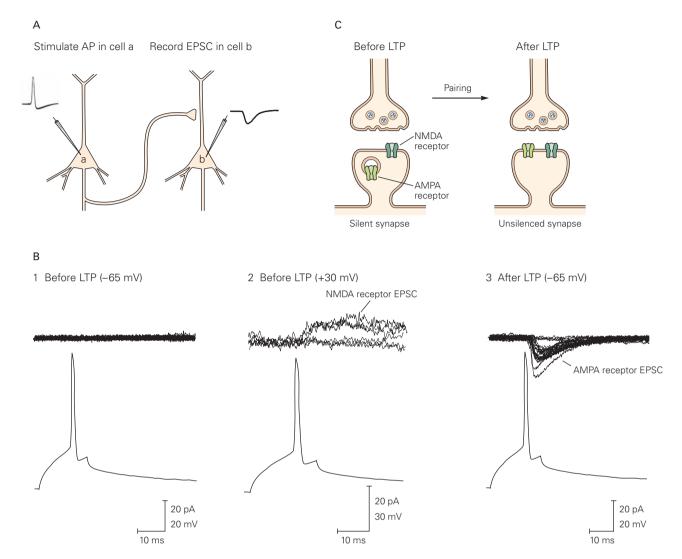

Figure 67–5 Unsilencing of silent synapses during longterm potentiation.

A. Intracellular recordings are obtained from a pair of hippocampal pyramidal neurons. An action potential is triggered in neuron a by a depolarizing current pulse and the resultant excitatory postsynaptic current (EPSC) produced in neuron b is recorded under voltage clamp conditions.

B. Effect of induction of LTP on silent synapses. Before induction of LTP there is no EPSC in cell b in response to an action potential in cell a when the membrane potential of neuron b is at its resting value of -65 mV (1). However, slow NMDA receptor-mediated EPSCs are observed when neuron b is

depolarized by the voltage clamp to +30 mV (2). LTP is then induced by pairing action potentials in neuron a with postsynaptic depolarization in neuron b to relieve Mg²+ block of the NMDA receptors. After this pairing fast AMPA receptor-mediated EPSCs are seen at -65 mV (3).

C. Mechanism of the unsilencing of silent synapses. Prior to LTP the dendritic spine contacted by a presynaptic CA3 neuron contains only NMDA receptors. Following induction of LTP intracellular vesicles containing AMPA receptors fuse with the plasma membrane at the synapse, adding new receptors on the spine.

large EPSPs at the resting potential mediated by AMPA receptors. These results indicate that LTP must involve an increase in the response of AMPA receptors to glutamate at the previously silent synapses, a process Roberto Malinow refers to as "AMPA fication."

How does the induction of LTP increase the response of AMPA receptors at previously silent synapses? The strong synaptic stimulation used to induce LTP will trigger glutamate release at both silent and nonsilent synapses on the same postsynaptic neuron.

This leads to the opening of a large number of AMPA receptors at the nonsilent synapses, which in turn produces a large postsynaptic depolarization. The depolarization will propagate throughout the neuron to relieve Mg²⁺ block of the NMDA receptors at both the nonsilent and silent synapses. At the silent synapses the Ca²⁺ influx through the NMDA receptors activates a biochemical cascade that ultimately leads to the insertion of clusters of AMPA receptors in the postsynaptic membrane from a pool of intracellular receptors stored in recycling endosomal vesicles. The fusion of these vesicles with the plasma membrane is triggered by the phosphorylation by protein kinase C of the cytoplasmic tail of the endosomal AMPA receptors (Figure 67–4B,C).

As discussed earlier, LTP is not a unitary process even at a single synapse. At Schaffer collateral synapses LTP generated by a brief 100 Hz tetanus depends solely on Ca²⁺ influx through NMDA receptors, whereas LTP induced by a 200 Hz tetanus depends on Ca²⁺ influx through both NMDA receptors and L-type voltage-gated Ca²⁺ channels. (A similar mechanism contributes to LTP in the direct entorhinal pathway to CA1 neurons.) This high-frequency form of LTP is expressed both through presynaptic mechanisms that enhance glutamate release and through postsynaptic mechanisms that increase the membrane response to glutamate. Thus both the induction and expression of LTP depend on a family of presynaptic and postsynaptic processes.

Because induction of LTP requires Ca²⁺ influx into the postsynaptic cell, the increase in transmitter release during LTP implies that the presynaptic cell must receive information from the postsynaptic cell that LTP has been induced. There is now evidence that Ca²⁺ activated second messengers in the postsynaptic cell, or perhaps Ca²⁺ itself, cause the postsynaptic cell to release one or more chemical messengers that diffuse to the presynaptic terminals to enhance release (see Figure 67–4B,C and Chapter 11). Importantly, these diffusible retrograde signals appear to affect only those presynaptic terminals that have been activated by the tetanic stimulation, thereby preserving synapse specificity.

Long-Term Potentiation in the Schaffer Collateral Pathway Follows Hebbian Learning Rules

The NMDA receptors endow LTP in the Schaffer collateral pathway with several interesting properties that have direct relevance to learning and memory. First, LTP in this pathway requires the near simultaneous activation of a large number of afferent axons, a feature called *cooperativity* (Figure 67–6). This requirement stems from the fact that relief of Mg²⁺ block of the NMDA receptor requires a large depolarization.

The second important property of LTP in the Schaffer collateral pathway is that it is associative.

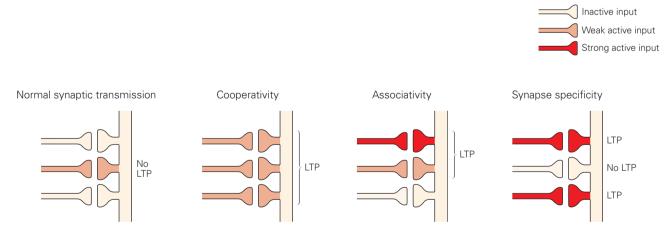

Figure 67–6 Long-term potentiation in CA1 pyramidal neurons of the hippocampus shows cooperativity, associativity, and synapse specificity. With normal synaptic transmission a single action potential in one or a few axons (weak input) leads to a small EPSP that is insufficient to expel Mg²+ from the NMDA glutamate receptor-channels and thus cannot induce LTP. This ensures that irrelevant stimuli are not remembered. The near-simultaneous activation of several weak inputs during strong activation (cooperativity) produces a suprathreshold

EPSP that triggers action potential firing and results in LTP in all pathways. Stimulation of strong and weak inputs together (associativity) causes LTP in both pathways. In this way a weak input becomes significant when paired with a powerful one. An unstimulated synapse does not undergo LTP in spite of the strong stimulation of neighboring synapses. This ensures that memories are selectively formed at active synapses (synapse specificity).

A weak synaptic input normally does not produce enough postsynaptic depolarization to induce LTP. However, if that weak input is coactivated or paired with a strong synaptic input that does produce suprathreshold depolarization, then the large depolarization will be able to propagate to the synapse with weak input, leading to relief of the Mg²⁺ blockade of the NMDA receptors in the postsynaptic membrane at that site and the induction of LTP.

The third key property of LTP is that it is *synapse specific*. If a particular synapse is not activated during a period of strong synaptic stimulation, the NMDA receptors at that site will not be able to bind glutamate and thus will not be activated despite the strong post-synaptic depolarization. As a result, that synapse will not undergo LTP.

Each of these three properties of cooperativity, associativity, and synapse specificity underlies key components of memory storage. Cooperativity ensures that only events of a high degree of significance, those that activate sufficient inputs, will result in memory storage. Associativity, like associative Pavlovian conditioning, allows an event (or conditioned stimulus) that has little significance in and of itself to be endowed with a higher degree of meaning if that event occurs just before or simultaneously with another more significant event (an unconditioned stimulus). Finally, synapse specificity ensures that inputs that convey information not related to a particular event will not be strengthened to participate in a given memory.

The finding that the induction of LTP in the Schaffer collateral pathway requires that presynaptic activity be strong enough to elicit firing in the postsynaptic neuron provides evidence for *Hebb's rule*, proposed in 1949 by the psychologist Donald Hebb as a theoretical mechanism for how neuronal circuits are modified by experience: "When an axon of cell A . . . excites cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A's efficiency as one of the cells firing B is increased." A similar principle is involved in fine-tuning synaptic connections during the late stages of development (see Chapter 56).

The Hebbian nature of LTP is best illustrated by the phenomenon of spike timing-dependent plasticity. Under most circumstances hippocampal neurons do not produce the high-frequency trains of action potentials typically used to induce LTP. However, a form of LTP can be induced by pairing a single presynaptic stimulus with the firing of a single action potential in the postsynaptic cell. In fact, this coincidence detection is very strict. In agreement with Hebb's postulate, the pairing protocol produces LTP only if the postsynaptic

cell fires a few milliseconds *after* the EPSP. That is, the presynaptic cell must fire before the postsynaptic cell. If the postsynaptic cell fires just before the EPSP, a long-lasting decrease in the size of the EPSP occurs (this long-term depression is described more fully below.) If the action potential occurs more than a hundred milliseconds before or after the EPSP, the synaptic strength will not change.

The pairing rules of spike timing-dependent plasticity result in large part from the cooperative properties of the NMDA receptor. If the postsynaptic spike occurs during the EPSP, the spike is able to relieve the Mg²⁺ blockade of the receptor at a time when the NMDA receptor-channel has been activated by the binding of glutamate. This leads to a large influx of Ca²⁺ through the receptor and the induction of LTP. However, if the postsynaptic action potential occurs prior to glutamate release, any relief from the Mg²⁺ block will occur when the gate of the receptor-channel is closed, because of the absence of glutamate. As a result there will be little influx of Ca²⁺ through the receptor to induce LTP.

These studies of the Schaffer collateral pathway indicate that two sequential associative mechanisms ensure that the induction of LTP is restricted to those synapses at which there is both presynaptic and postsynaptic activity, in accord with Hebb's learning rule. The first mechanism is the associative property of the NMDA glutamate receptor. The second is the selective action of retrograde messengers released from the postsynaptic cell at only those presynaptic sites that are active. As we saw in Chapter 66, these two associative mechanisms in series also contribute to associative classical conditioning in *Aplysia* and in the amygdala. Thus mechanisms of synaptic plasticity important for learning and memory have been conserved throughout evolution of the species at broad classes of synapses and for distinct forms of learning.

Long-Term Potentiation Has Early and Late Phases

Long-term potentiation has two phases. One train of action potentials produces a phase of LTP lasting 1 to 3 hours called *early LTP*. This component, which is the phase we have been considering up to now, does not require new protein synthesis, cAMP, or PKA activation. However, four or more trains of synaptic stimulation induce a late LTP that lasts up to 24 hours; this late LTP does require cAMP and PKA, as well as changes in gene transcription and the synthesis of new proteins (Figure 67–7).

Although the mechanisms for early LTP in the Schaffer collateral and mossy fiber pathways are quite different, the mechanisms for late LTP in the two pathways appear similar. In both pathways late LTP recruits the cAMP and PKA signaling pathway, which recruits the cAMP response element binding protein (CREB) transcription factor, leading to the synthesis of new mRNAs and proteins.

How do the synaptic mechanisms for the expression of early and late LTP differ? Quantal analysis (see Chapter 12) was used to examine synaptic transmission between a single presynaptic CA3 neuron and a single postsynaptic CA1 cell (Figure 67–8).

Prior to LTP a CA3 neuron typically forms only one functional synapse with a CA1 neuron. At this synapse a presynaptic action potential releases with low probability a single vesicle of transmitter. This weak connection between a single CA3 and single CA1 neuron means that a large number of CA3 neurons must be co-activated to trigger a spike in the postsynaptic CA1 cell. Following induction of early LTP, the probability that a presynaptic action potential will release a vesicle is increased (Figure 67–8C).

Induction of the late phase of LTP by direct application of a chemical analog of cAMP dramatically changes the response to synaptic stimulation. Under these conditions a presynaptic action potential elicits a very large EPSP through the release of multiple quanta of transmitter (Figure 67–8D). Because each release site (active zone) in the presynaptic terminal is thought to release at most one vesicle in an all-ornone fashion, the increase in the number of quanta indicates that late LTP recruits new presynaptic release sites apposed to new clusters of AMPA receptors in the postsynaptic membrane. Moreover, the formation of new synapses requires new protein synthesis, consistent with the idea that late LTP involves a growth process. Light microscopic imaging studies of live

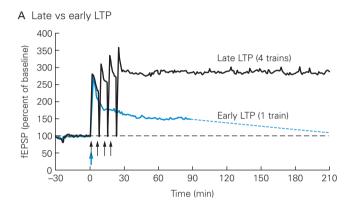

Figure 67–7 Early and late phases of long-term potentiation in the CA1 region of the hippocampus.

A. Early LTP is induced by a single tetanus lasting 1 second at 100 Hz. Late LTP is induced by four tetani given 10 minutes apart. Early LTP of the fEPSP lasts only 1 to 2 hours, whereas the late LTP lasts more than 8 hours (only the first 3.5 hours are shown). (Reproduced, with permission, from Kandel 2001.)

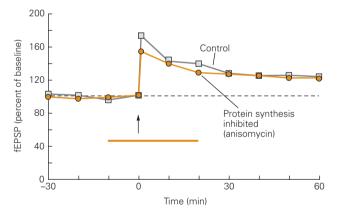

- **B.** Early LTP induced by one tetanus is not blocked by anisomycin, an inhibitor of protein synthesis. Bar indicates application of anisomycin during the LTP induction protocol. (Reproduced, with permission, from Huang and Kandel 1994.)
- C. Late LTP induced by three trains of stimulation is blocked by anisomycin. (Three or four trains can be used to induce late LTP.) (Reproduced, with permission, from Huang and Kandel 1994.)

neurons in hippocampal slices provide direct evidence that LTP induces the formation of new dendritic spines, the sites of new excitatory synaptic input.

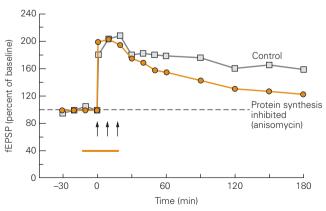

Like sensitization of the gill-withdrawal reflex in *Aplysia*, late LTP in the Schaffer collateral pathway is synapse specific. When two independent sets of synapses in the same postsynaptic CA1 neuron are stimulated

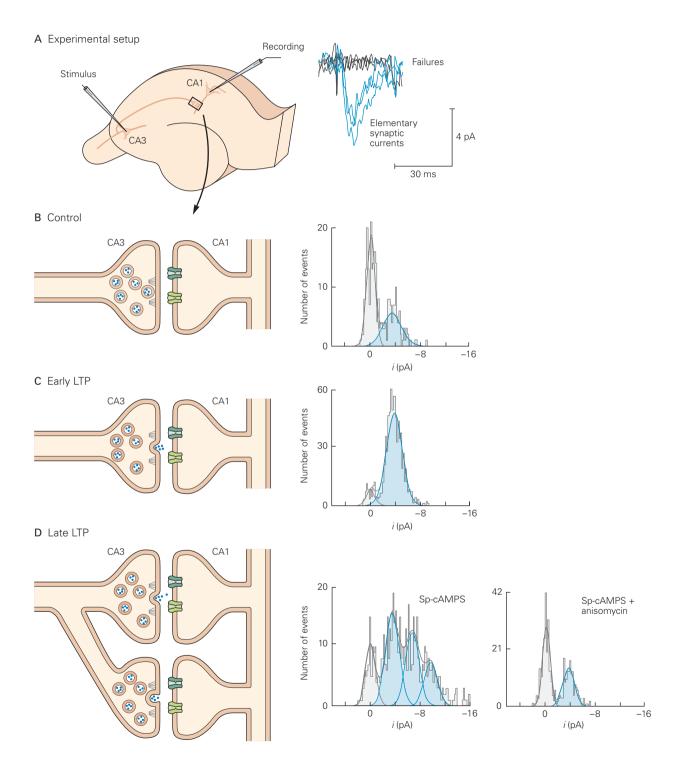

B Early LTP does not require protein synthesis

C Late LTP requires protein synthesis

using two electrodes spaced some distance apart, the application of four trains of tetanic stimulation to one set of synapses induces late LTP only at the activated synapses; synaptic transmission at the second set of nonstimulated synapses is not altered. However, Uwe Frey and Richard Morris found that if a single tetanus is applied to the second set of synapses soon after the four tetani are applied to the first set, the single train is able to induce late LTP at the synapses it activates. This phenomenon is similar to the synapse-specific capture of long-term facilitation at the sensory-motor neuron synapses in Aplysia (see Chapter 66). At the Schaffer collateral synapses the single tetanus somehow marks the activated synapses allowing them to respond to, or capture, the new proteins synthesized in response to signals from the synapses that received the four tetani.

How can a few brief trains of synaptic stimulation produce such long-lasting increases in synaptic transmission? Studies from Todd Sacktor have shown that the maintenance of late LTP depends on a novel isoform of protein kinase C termed PKMζ (PKM zeta). Most isoforms of PKC contain both a regulatory domain and a catalytic domain (see Chapter 11). Binding of diacylglycerol, phospholipids, and Ca²+ to the regulatory domain of PKC relieves its inhibitory binding to the catalytic domain, which is then free to phosphorylate its protein substrates. In contrast, PKMζ lacks a regulatory domain and so is constitutively active.

Levels of PKM ζ in the hippocampus are normally low. Tetanic stimulation that induces LTP leads to an

increase in synthesis of PKM ζ through enhanced translation of its mRNA. This mRNA is present in the CA1 neuron dendrites, enabling its local translation to rapidly alter synaptic strength. Blockade of PKM ζ with a specific inhibitor does not block early LTP but does block late LTP. Moreover, application of the PKM ζ blocker several hours after the LTP induction protocol can reverse late LTP after it has been established. This result indicates that the maintenance of late LTP requires the persistent and ongoing activity of PKM ζ , which leads to the persistent increase in insertion of AMPA receptors in the postsynaptic membrane (Figure 67–9).

Spatial Memory Depends on Long-Term Potentiation in the Hippocampus

Long-term potentiation is an experimentally induced change in synaptic strength produced by strong direct stimulation of neural pathways. Does this form of synaptic change occur physiologically for explicit memory storage? If so, how does it affect the normal processing of information for memory storage in the hippocampus?

To date a large number of experimental approaches have shown that inhibiting LTP interferes with spatial memory. One spatial memory test uses a pool filled with an opaque fluid (the Morris water maze). To escape from the liquid a mouse must find a platform submerged below the surface of the fluid and completely

Figure 67–8 (Opposite) Quantal analysis of early and late phases of long-term potentiation. (Reproduced, with permission, from Bolshakov et al. 1997.)

A. When a single presynaptic CA3 cell is stimulated to fire an action potential, it produces a small excitatory postsynaptic current (EPSC) in a postsynaptic CA1 cell recorded under voltage clamp conditions. When the CA3 cell is stimulated successively at a frequency too low to induce LTP or LTD, the EPSC varies from stimulus to stimulus. The stimulus either evokes an EPSC (a success) or does not evoke any measurable response (a failure). The amplitude of the successes is equal to that of the miniature EPSC, the elementary or quantal response.

B. Before LTP, stimulation of the presynaptic cell results in many failures; the synapse has a low probability of releasing a vesicle. The distribution of the EPSC amplitudes can be approximated by two Gaussian curves, one centered on zero current (the failures) and the other centered on –4 pA (the successful responses). These histograms are consistent with the type of synapse illustrated here, in which a single CA3 cell makes a single synaptic connection with a CA1 cell. This connection has a single active zone from which a single vesicle is released in an all-or-none manner (failures or successes) in response to successive stimuli. The postsynaptic membrane contains both

NMDA and AMPA receptors, the latter of which are responsible for the rapid EPSC at negative potentials.

C. Once early LTP has been induced, the probability of release increases significantly, leading to a decrease in the fraction of failures and an increase in the fraction of successes. The EPSC histogram is again fitted by two Gaussian curves, consistent with the view that there is still only a single release site that releases at most a single vesicle but now with a high probability of release. (This study examined LTP at non-silent synapses under conditions where insertion of new AMPA receptors was not observed.)

D. When late LTP is induced by prolonged application of a membrane-permeable analog of cAMP (Sp-cAMPS), the distribution of successful responses is no longer fitted by a single Gaussian curve. Instead, three or four Gaussian curves are fitted, suggesting that a single presynaptic action potential releases multiple quanta (synaptic vesicles) of transmitter. These effects are blocked by anisomycin, an inhibitor of protein synthesis. The increase in number of quanta is consistent with the growth of new sites of synaptic transmission between the presynaptic and postsynaptic neurons. (Sp-cAMPS, Sp-diastereomer of adenosine cyclic 3',5'-phosphorothioate.)

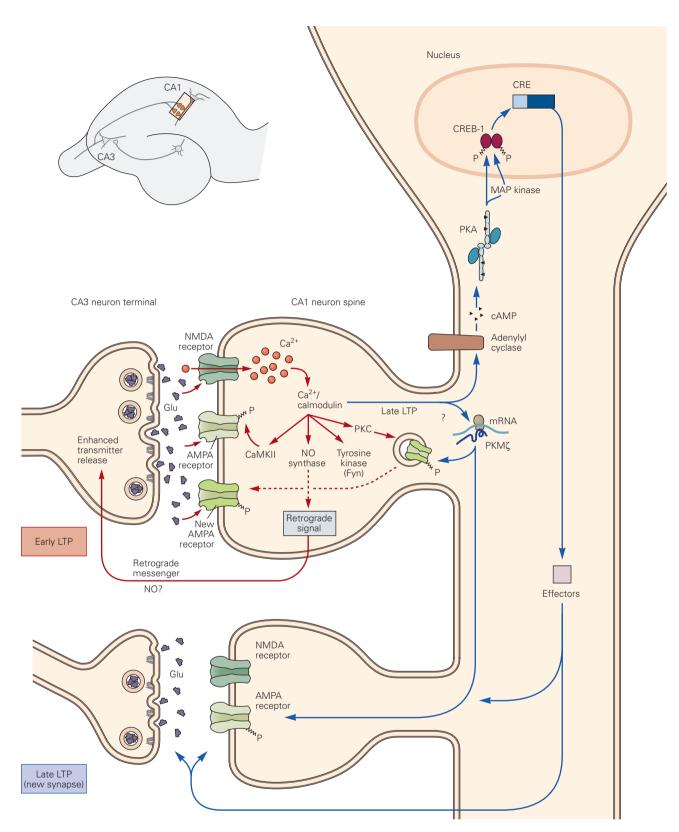

Figure 67–9 A model for the molecular mechanisms of early and late phases of long-term potentiation. A single tetanus induces early LTP by activating NMDA receptors, triggering Ca²⁺ influx into the postsynaptic cell and the activation of a set of second messengers. With repeated tetani the Ca²⁺ influx also recruits an adenylyl cyclase, which generates cAMP that activates PKA. This leads to the activation of MAP kinase, which translocates to the nucleus where it phosphorylates CREB-1. CREB-1 in turn activates transcription of targets

(containing the CRE promoter) that are thought to lead to the growth of new synaptic connections. Repeated stimulation also activates translation in the dendrites of mRNA encoding PKM ζ , a constitutively active isoform of PKC. This leads to a long-lasting increase in the number of AMPA receptors in the postsynaptic membrane. A retrograde signal, perhaps NO, is thought to diffuse from the postsynaptic cell to the presynaptic terminal to enhance transmitter release.

hidden from view. The animal is released at random locations around the pool and initially encounters the platform by chance. However, in subsequent trials the mouse quickly learns to locate the platform and then remembers its position based on spatial *contextual cues*—markings on the walls of the room in which the pool is located. This task requires the hippocampus. In a *noncontextual* version of this test the platform is raised above the water surface or marked with a flag so that it is visible, permitting the mouse to navigate directly to the platform using brain pathways that do not require an intact hippocampus.

When NMDA receptors are blocked by injection of a pharmacological antagonist into the hippocampus, the animal can find the visible platform in the noncontextual version of the task but cannot remember the location of the hidden platform in the contextual version. These experiments thus suggest that some mechanism involving NMDA receptors in the hippocampus, perhaps LTP, is involved in spatial learning. As we saw above, NMDA receptors are required for the induction but not for the persistence or maintenance of LTP. Similarly, injection of an NMDA receptor blocker into the hippocampus *after* an animal has learned a spatial memory task does not inhibit subsequent memory recall for that task.

As we also saw above, PKM ζ is required for the maintenance of LTP but is not involved in its initial induction. Todd Sacktor and his colleagues have found a corresponding requirement for PKM ζ in the persistence of memory. Thus injection of a pharmacological inhibitor of PKM ζ into the hippocampus 1 day after an animal has been trained on a spatial task disrupts the memory for that task.

More direct evidence for the correlation of memory and LTP comes from experiments with mutant mice that have genetic lesions that interfere with LTP. One interesting mutation is produced by the genetic deletion of the NR1 subunit of the NMDA receptor. Neurons lacking this subunit fail to form functional NMDA receptors. Mice with a general deletion of the subunit die soon after birth, indicating the importance of these receptors for neural function. However, it is possible to generate lines of mutant mice in which the NR1 deletion is restricted to CA1 pyramidal neurons and occurs only 1 or 2 weeks after birth (Box 67–1). These mice survive into adulthood and show a loss of LTP in the Schaffer collateral pathway. This disruption is highly localized; nevertheless the mutant mice have a serious deficit in spatial memory (Figure 67–12).

Although it is perhaps not surprising that genetic manipulations can impair neuronal function, in some cases genetic changes can actually enhance both hippocampal LTP and spatial learning and memory. One of the first examples of such an enhancement comes from studies of a mouse mutant that overexpresses the NR2B subunit of the NMDA receptor. This subunit is normally present at early stages of development but is downregulated at adult hippocampal synapses. Receptors that incorporate this subunit allow more Ca²⁺ influx than those that do not. In mutant mice that overexpress the NR2B subunit LTP is enhanced, presumably because of an enhancement in Ca²⁺ influx. Importantly, learning and memory for several different tasks are also enhanced (Figure 67–13).

One concern with gene knockouts or transgene expression is that such mutations might lead to subtle developmental abnormalities. That is, changes in the size of LTP and spatial memory in the mutant animals could be the result of an early developmental alteration in the wiring of the hippocampal circuit rather than a change in the basic mechanisms of LTP. This possibility can be addressed by reversibly turning on and off a transgene that interferes with LTP (see Box 67–1).

Reversible gene expression has been used to explore the role of the enzyme CaMKII, whose function in LTP was discussed above. After a brief exposure to Ca²⁺, CaMKII can be converted to a Ca²⁺ independent state through its autophosphorylation at threonine-286 (Thr286). This ability to become persistently active in response to a transient Ca²⁺ stimulus led to the suggestion that CaMKII may act as a simple molecular switch to maintain memory. Mutation of Thr286 to the negatively charged amino acid aspartate mimics the effect of autophosphorylation at Thr286 and converts the CaMKII to a Ca²⁺-independent form.

Transgenic expression of this dominant mutation of CaMKII (CaMKII–Asp286) results in a systematic shift in the relation between stimulus frequency during a tetanus and the resultant change in synaptic strength during long-term plasticity. In the transgenic mice intermediate-frequency tetanic stimulation at 10 Hz, which normally induces a small amount of LTP, induces long-term depression of synaptic transmission in the Schaffer collateral pathway (Figure 67–14A). In contrast, Schaffer collateral LTP in response to a 100 Hz tetanus is not altered. The defect in synaptic plasticity with intermediate frequency stimulation is associated with an inability of the mutant mice to remember spatial tasks (Figure 67–14C). However, the defects in LTP and in spatial memory can be fully rescued when the mutant gene is switched off in the adult, thereby showing that the memory defect is not due to a developmental abnormality (Figure 67–14).

These several experiments using restricted knockout and overexpression of the NMDA receptor and

Box 67–1 Restricting Gene Knockout and Regulating Transgenic Expression

Biological analysis of learning requires the establishment of a causal relation between specific molecules and learning. In the past this relationship was difficult to demonstrate in mammals but now can be studied successfully in mice either by the use of transgenes or gene knockout.

With gene knockout, deletion of a specific gene is induced in embryonic stem cells through homologous recombination (see Figure 3–8). Experiments using transgenes and gene knockout have made it possible to examine the relationship of NMDA receptors and different second-messenger-dependent protein kinases to long-term potentiation in the hippocampus and to spatial learning.

Conventional gene knockout is unrestricted; animals inherit the genetic deletion in all of their cell types. Global genetic deletion may cause developmental defects that interfere with the later functioning of neural circuits important for memory storage. As a result, interpretation of the results from experiments using conventional gene knockout run into two types of problems.

First, it is often difficult to exclude the possibility that the abnormal phenotype observed in mature animals results directly or indirectly from a developmental defect rather than because that gene plays a specific, active role in learning and memory. Second, global gene knockout makes it difficult to attribute abnormal phenotypes to a particular type of cell or specific region within the brain.

Regional Control of Gene Expression

To improve the utility of gene knockout technology, methods have been developed that restrict deletions to cells in a specific tissue or at specific points in an animal's development. One method of regional restriction exploits the Cre/loxP system. The Cre/loxP system is a site-specific recombination system, derived from the P1 phage, in which the phage enzyme Cre recombinase catalyzes recombination between 34 bp loxP recognition sequences, which are normally not present in animal genomes.

The *loxP* sequences can be inserted into the genome of embryonic stem cells by homologous recombination such that they flank one or more exons of a gene of interest (called a *floxed* gene). When the stem cells are injected into an embryo, a mouse can be eventually bred in which the gene of interest is floxed and still functional in all cells of the animal.

A second line of transgenic mice can then be generated that expresses Cre recombinase under the control of a neural promoter sequence that is normally expressed in a restricted brain region. By crossing the Cre transgenic line of mice with the line of mice with the floxed gene of interest, the gene will only be deleted in those cells that express the Cre transgene (Figure 67–10).

In the example shown in Figure 67–10 the gene encoding the NR1 (or GluN1) subunit of the NMDA

glutamate receptor has been flanked with *loxP* elements and then crossed with a mouse line expressing Cre recombinase under control of the *CaMKII* promoter, which normally is expressed in forebrain neurons. In this particular line expression was fortuitously limited to the CA1 region of the hippocampus, resulting in selective deletion of the NR1 subunit in this brain region. Because the *CaMKII* promoter only activates gene transcription postnatally, early developmental changes are minimized by this strategy.

Temporal Control of Gene Expression

In addition to regional restriction of gene expression, effective use of genetically modified mice requires control over the timing of gene expression. The ability to turn a transgene on and off gives the investigator an additional degree of flexibility and can exclude the possibility that any abnormality observed in the phenotype of the mature animal is the result of a developmental defect produced by the transgene. This can be done in mice by constructing a gene that can be turned on or off with a drug.

One starts by creating two lines of mice. Line 1 carries a particular transgene, for example *CaMKIIα-Asp286*, a mutated form of the gene *CaMKIIα* coding for a constitutively active kinase. Instead of being attached to its normal promoter, the transgene is attached to the promoter *tetO* that is ordinarily found only in bacteria (Figure 67–11).

This promoter cannot by itself turn on the gene; it needs to be activated by a specific transcriptional regulator. Thus the second line of mice expresses a second transgene that encodes a hybrid transcription factor, the tetracycline transactivator (tTA), which recognizes and binds to the *tetO* promoter. Expression of tTA is placed under the control of a region-specific promoter, such as the promoter for *CaMKIIα*.

When the two lines of mice are mated, some of the offspring will carry both transgenes. In these mice the tTA binds to the *tetO* promoter and activates the mutated *CaMKII*α gene. This mutant causes abnormalities in long-term potentiation (see Figure 67–14).

But when the antibiotic doxycycline (similar to tetracycline) is administered, the drug binds to the transcription factor tTA, causing it to undergo a change in shape that makes it come off the promoter. In the presence of the antibiotic, cells stop expressing CaMKIIα-Asp286 and long-term potentiation returns to normal, demonstrating that the transgene exerts its effect by perturbing signaling in the adult brain rather than by interfering with neural development.

One can also generate mice that express a mutant form of tTA called reverse tTA (rtTA). This transactivator will not bind to *tetO* unless the animal is fed doxycycline. In this case the transgene is always turned off unless the drug is given.

Figure 67-10 The Cre/loxP system for gene knockout.

A. A line of mice is bred in which the gene encoding the NR1 subunit of the NMDA receptor has been flanked by loxP genetic elements (transgenic mouse line 1). These so-called "floxed NR1" mice are then crossed with a second line of mice in which a transgene coding for Cre recombinase is placed under the control of a transcriptional promoter specific to a cell type or a tissue type (transgenic mouse line 2). In this example the promoter from the $CaMKII\alpha$ gene is used to drive expression of the Cre gene. In progeny that are homozygous for the floxed gene and that carry the Cre recombinase transgene, the floxed gene will be deleted by Cre-mediated loxP recombination only in

cell type(s) in which the promoter driving *Cre* expression is active.

B. In situ hybridization is used to detect mRNA for the NR1 subunit in hippocampal slices from wild-type and mutant mice that contain two floxed NR1 alleles and express Cre recombinase under the control of the *CaMKIIα* promoter. Note that NR1 mRNA expression (**dark staining**) is greatly reduced in the CA1 region of the hippocampus but remains normal in CA3 and the dentate gyrus (**DG**). (Reproduced, with permission, from Tsien, Huerta, and Tonegawa 1996.)

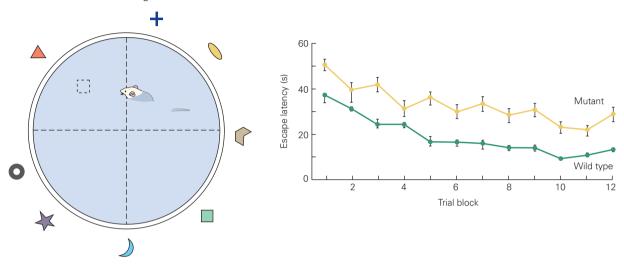

Figure 67–11 The tetracycline system for temporal and spatial regulation of transgene expression. Two independent lines of transgenic mice are bred. One line expresses, under the control of the *CaMKIIα* promoter, the tetracycline transactivator (tTA), an engineered protein incorporating a bacterial transcription factor that recognizes the bacterial *tetO* operon. The second line contains a transgene of interest—here encoding a constitutively active form of CaMKII (*CaMKII*–Asp286) that makes the kinase persistently active in the absence of Ca²⁺—whose expression is under control of *tetO*. When these two lines

are mated the offspring express the tTA protein in a pattern restricted to the forebrain. When the tTA protein binds to tetO it will activate transcription of the downstream gene of interest. Tetracycline (or doxycycline) given to the offspring binds to the tTA protein and causes a conformational change that leads to the unbinding of the protein from tetO, blocking transgene expression. In this manner mice will express CaMKII–Asp286 in the forebrain, and this expression can be turned off by administering doxycycline to the mice. (Reproduced, with permission, from Mayford et al. 1996.)

B Morris water maze learning

C Probe trial test of memory

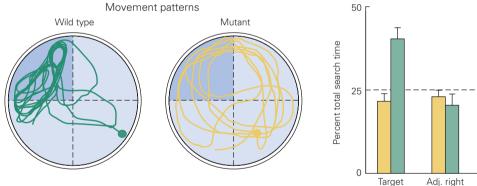

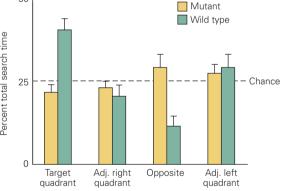

Figure 67–12 Long-term potentiation, and spatial learning and memory are impaired in mice that lack the NMDA receptor in the CA1 region of the hippocampus. (Reproduced, with permission, from Tsien, Huerta, and Tonegawa 1996.)

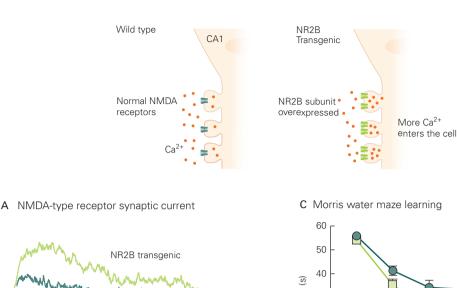

A. LTP is abolished in mice in which the NMDA receptor is selectively deleted in CA1 pyramidal neurons by knocking out the NR1 subunit gene. Field EPSPs were recorded in response to Schaffer collateral stimulation. Tetanic stimulation at 100 Hz for 1 s (arrow) caused a large potentiation in wild-type mice but failed to induce LTP in the NMDA receptor knockout (mutant) mice.

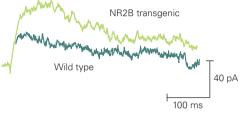

B. Mice that lack the NMDA receptor in CA1 pyramidal neurons have impaired spatial memory. A platform (dashed square) is submerged in an opaque fluid in a circular tank (the Morris water maze). To avoid remaining in the water the mice have to

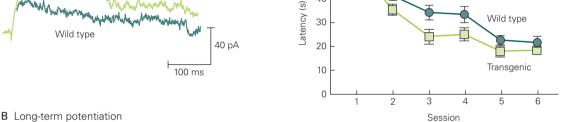

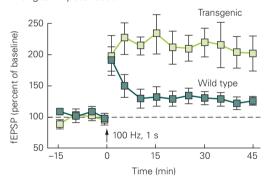

find the platform using spatial (contextual) cues on the walls surrounding the tank, and then climb onto the platform. The graph shows escape latency or the time required by mice to find the hidden platform in successive trials. The mutant mice display a longer escape latency in every block of trials (four trials per day) than do the wild-type mice. Also, mutant mice do not reach the optimal performance attained by the control mice after 12 training days, even though they show some improvement with training.

C. After the mice have been trained in the Morris maze the platform is taken away. In this probe trial the wild-type mice spend a disproportionate amount of time in the quadrant that formerly contained the platform (the target quadrant), indicating that they remember the location of the platform. Mutant mice spend an equal amount of time (25%) in all quadrants, ie, they perform at chance level, indicating deficient memory.

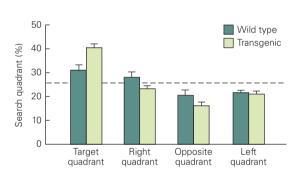

Figure 67–13 Learning and memory are enhanced in mice that overexpress the NR2B subunit of the NMDA glutamate receptor. (Reproduced, with permission, from Tang et al. 1999.)

A. The amplitude of the current generated by the NMDA receptors in response to a brief pulse of glutamate is enhanced and its time course prolonged in hippocampal neurons obtained from mice that contain a transgene that expresses higher levels of the NR2B subunit compared to wild-type mice.

B. Long-term potentiation produced by tetanic stimulation of the Schaffer collateral synapses is greater in the transgenic mice than in wild-type mice.

C. Spatial learning is enhanced in the transgenic mice as demonstrated in the upper plot. The rate of learning in a Morris water maze (the reduction in time to find the hidden platform, or escape latency) is faster in transgenic mice than in wild-type. Spatial memory is also enhanced in the transgenic mice as demonstrated in the probe trial (lower plot). Transgenic mice spend more time in the target quadrant, which previously contained the hidden platform, than do wild-type mice (see Figure 67-12C).

regulated overexpression of CaMKII-Asp286 make it clear that the molecular pathways important for LTP in the Schaffer collateral pathway are also required for spatial memory. However, in addition to receiving input through the Schaffer collaterals, CA1

neurons also receive excitatory input from the entorhinal cortex. Synaptic plasticity at the entorhinal inputs in CA1 may also contribute to spatial learning and memory. The HCN1 hyperpolarization-activated cation channel is strongly expressed in the very distal

dendrites of CA1 neurons, the site of the entorhinal inputs. These channels are partially open at the resting potential, which decreases the membrane resistance $(R_{\rm m})$ of the dendrite. This reduces the size of the EPSP in response to a given excitatory synaptic current $(\Delta V_{\rm EPSP} = I_{\rm EPSP} \times R_{\rm m})$ and decreases the membrane time

constant ($\tau_m = R_m \times C_m$). The net effect is a reduction in the spatial and temporal integration of EPSPs in the perforant path.

Mice lacking the HCN1 subunit show markedly enhanced temporal summation of EPSPs in the distal dendrites in response to a tetanus because of the

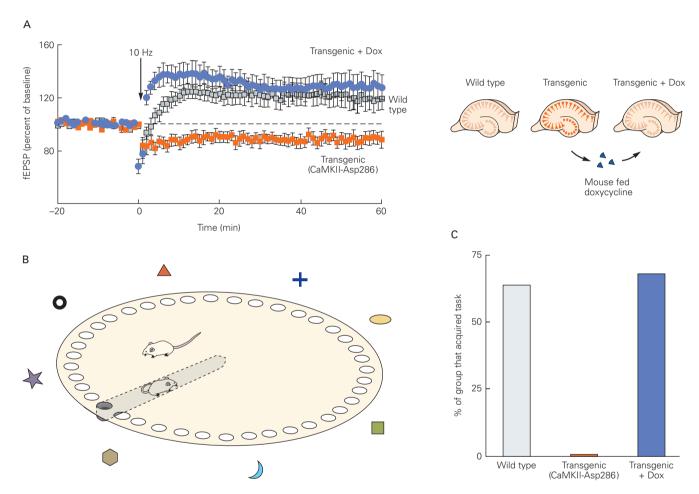

Figure 67–14 Deficits in long-term potentiation and spatial memory due to a transgene are reversible. (Reproduced, with permission, from Mayford et al. 1996.)

A. An LTP deficit is seen in hippocampal slices from transgenic mice that overexpress a constitutively active form of CaMKII, CaMKII-Asp286. Expression of this kinase is under control of *tetO* and the tTA transcription factor (see Box 67–1). Four groups of mice were tested: transgenic mice that are fed doxycycline (Dox), which blocks expression of the kinase; transgenic mice without doxycycline, in which the kinase is expressed; and wild-type mice with and without doxycycline. In wild-type mice a 10 Hz tetanus induces LTP; doxycycline has no effect (data are not shown). In the transgenic mice the tetanus fails to induce LTP but causes a small synaptic depression. In the transgenic mice that are fed doxycycline the deficit in LTP is reversed.

B. The effect of the kinase on spatial memory was tested in the Barnes maze. This consists of a platform with 40 holes, one of which leads to an escape tunnel that allows the mouse to exit the platform. The mouse is placed in the center of the platform. Mice do not like open, well-lit spaces and therefore try to escape from the platform by finding the hole that leads to the escape tunnel. The most efficient way of learning and remembering the location of the hole (and the only way of meeting the criteria set for the task by the experimenter) is by using distinctive markings on the four walls as cues for hippocampal-dependent spatial memory.

C. Transgenic mice that express the CaMKII-Asp286 kinase and receive doxycycline perform as well as wild-type mice in learning the Barnes maze task (approximately 65% of animals learn the task), whereas transgenic mice without the doxycycline (in which the kinase is highly expressed) do not learn the task.

increased membrane time constant. This contributes to a large increase in the magnitude of LTP at the perforant path synapses. In contrast, the same mice show relatively little change in EPSPs or LTP at the Schaffer collateral synapses, which are formed on more proximal regions of CA1 dendrites where expression of HCN1 is relatively modest. Importantly, the mutant mice get smarter, exhibiting a significantly faster rate at which they learn to find the hidden platform in the Morris maze relative to littermates that express normal levels of HCN1. Such experiments support the view that LTP at the most distal perforant path inputs to CA1 neurons also contributes to spatial learning and memory.

The preceding experiments demonstrate that a wide range of pharmacological and genetic manipulations that alter LTP are correlated with changes in spatial learning and memory. However, such results do not directly show that spatial learning and memory are actually associated with an enhancement in hippocampal synaptic transmission. Mark Bear and colleagues addressed this question by monitoring the strength of synaptic transmission at the Schaffer collateral CA1 synapses in vivo in rats using an array of extracellular recording electrodes.

Recordings were made of synaptic strength as rats were trained to avoid one side of a box through administration of a foot shock. These experiments show that after training there is a small but significant increase in the amplitude of synaptic transmission at a subset of the recording electrodes. Importantly, at electrode sites where the enhancement is greatest, LTP in response to tetanic stimulation through an independent electrode is diminished. This result implies that the enhanced synaptic transmission following spatial training is actually caused by the induction of LTP; because the amount of LTP at a given synapse is finite, the prior induction of LTP during learning occludes the subsequent induction of LTP by electrical stimulation. This effect is similar to the occlusion of LTP in the amygdala during fear learning, as discussed in Chapter 66.

A Spatial Map of the External World Is Formed in the Hippocampus

In 1971 John O'Keefe and John Dostrovsky made the remarkable discovery in rats that the hippocampus contains a cognitive map of an animal's spatial environment. An animal's familiarity with a particular environment is represented in the hippocampus by the firing pattern of populations of pyramidal cells, termed place cells, in the CA3 and CA1 regions. A place cell fires when an animal enters a certain location in a specific

environment, the cell's *place field* (Figure 67–15). The population of place fields specify the environment. When the animal enters a new environment new place fields are formed within minutes and are stable for weeks to months. Thus, if one records the electrical activity of a number of place cells it is possible to predict where the animal is in its environment. In this manner the hippocampus is thought to constitute a cognitive map of the animal's surroundings.

O'Keefe's demonstration of place cells provided the first evidence for a neural representation of the environment that allows an animal to move deliberately around the world. The idea of a cognitive map was predicted earlier by the great cognitive psychologist Edward Tolman. He proposed that somewhere in the brain there must be a representation of the environment. This cognitive map is not topographic or egocentric in its organization, like the maps for touch or vision on the surface of the cerebral cortex. Rather the map is allocentric (or geocentric); it is fixed with respect to a point in the outside world.

How is the spatial map formed? What type of spatial information is carried by the afferent connections to the hippocampal place cells? In 2005 Edvard and May-Britt Moser and their colleagues in Norway discovered that neurons in the medial entorhinal cortex, whose axons form the perforant pathway to the hippocampus, map space in a very different manner from the hippocampal place cells. Instead of firing when the animal is in a unique location, like the place cells, the entorhinal neurons, termed grid cells, fire whenever the animal is at any of several, regularly spaced positions forming a triangular grid-like array. This grid allows the animal to locate its body within a Cartesian-like external coordinate system that is independent of context, landmarks, or specific markings. The gridded spatial information conveyed by the entorhinal inputs is transformed within the hippocampus into unique spatial locations represented by the firing of place cells.

Once the firing pattern of a population of hippocampal neurons is formed for a given environment, how is it maintained? Because the place cells are the same hippocampal pyramidal neurons that undergo experimental LTP, a natural question is whether LTP is important. This question was addressed in experiments in mice in which LTP was disrupted.

Surprisingly, in mice lacking the NR1 subunit of the NMDA receptor, hippocampal pyramidal neurons still fire in place fields despite the fact that LTP is blocked. Thus this form of LTP is not required for the transformation of spatial sensory information into place fields. However, place fields of hippocampal neurons in the mutant mice are larger and fuzzier in outline than

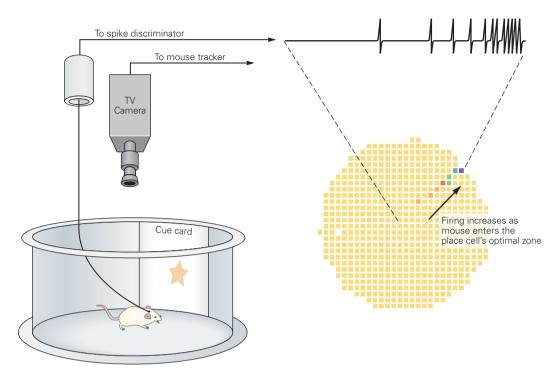

Figure 67–15 The firing patterns of pyramidal cells in the hippocampus create an internal representation of the animal's location in its surroundings. Electrodes implanted in the hippocampus of a mouse are attached to a recording cable, which is connected to an amplifier attached to a computer-based spike-discrimination program. The mouse is placed in a cylinder with an overhead TV camera that transmits to a device that detects the position of the mouse. The cylinder also contains a visual cue to orient the animal. Spikes in individual hippocampal pyramidal neurons (place cells) are detected by

the spike discrimination program. The firing rate of each cell is then plotted as a function of the animal's location in the cylinder. This information is visualized as a two-dimensional map of color-coded firing rates for the cell, from which the cell's place field can be determined. Yellow, orange, red, green, blue, and purple pixels show regions with progressively increasing rates of firing. The place field is the location in space that elicits optimal firing in the cell. (Adapted, with permission, from Muller, Kubie, and Ranck 1987.)

those in normal animals. In a second experiment with mutant mice, late LTP and long-term spatial memory were selectively disrupted by expression of a transgene that encodes a protein inhibitor of protein kinase A. In these mice place fields also form but the firing patterns of individual cells are stable only for an hour or so (Figure 67–16). Thus late LTP is required not for the formation but for long-term stabilization of place fields.

These experiments raise a final question: To what degree do these maps of an animal's surroundings mediate explicit memory? In humans explicit memory is defined as the conscious recall of facts about people, places, and objects. Although consciousness cannot be studied empirically in the mouse, selective attention, which is required for conscious recall, can be examined.

When mice are presented with different behavioral tasks, the long-term stability of a neuron's place field correlates strongly with the degree of attention required

to perform the task. When a mouse does not attend to the space it walks through, place fields form but are unstable after 3 to 6 hours. Animals with unstable place fields are unable to learn a spatial task. However, when a mouse is forced to attend to the space, for example as it forages for food, the place fields are stable for days.

How does this attentional mechanism work? Studies in primates have shown the importance of the prefrontal cortex and the modulatory dopaminergic system during attention. Indeed, the formation of stable place fields in mice requires the action of dopamine on the D_1/D_5 type of receptor, which stimulates adenylyl cyclase, leading to production of cAMP and activation of PKA. This demonstrates that, rather than being a form of implicit memory that is stored and recalled without conscious effort, long-term memory of a stably formed place field requires the animal to attend to its environment, as is the case for explicit memory in humans.

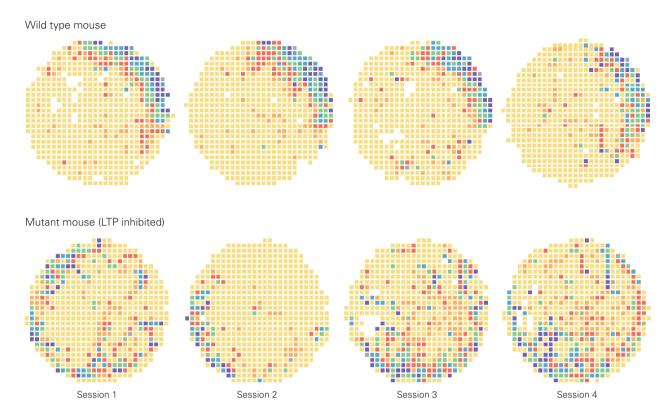

Figure 67–16 Disruption of long-term potentiation alters the stability of place field formation in hippocampal cells. Color-coded firing-rate maps (see Figure 67–15) show the place fields recorded in four successive sessions from a single hippocampal pyramidal neuron in a wild-type mouse and from a neuron in a mutant mouse that expresses the persistently active CaMKII (which inhibits the induction of LTP). Before each recording session the animal is taken out of the cylinder and

sometime later reintroduced into it. In each of the four sessions the place field for the cell in the wild-type animal is stable. In this example the place cell fires whenever the animal is in the upper right region of the enclosure. By contrast, the place field of the cell in the mutant mouse is unstable across the different sessions. (Reproduced, with permission, from Rotenberg et al.

Different Subregions of the Hippocampus Are Required for Pattern Separation and for Pattern Completion

Explicit memory is used to store facts (semantic memory) and episodes (episodic memory). Successful storage and recall of explicit memory requires the ability to distinguish between two closely related images, episodes, or spatial configurations—an ability called *pattern separation*. Explicit memory can also use partial cues to retrieve previously stored memories by filling in an incomplete pattern based on preexisting knowledge—an ability called *pattern completion*. Both capabilities are essential for optimal memory performance. We need to distinguish similar memories when the differences between them are important, and we need to recall memories when only partial clues for recall are available.

A variety of cell-physiological and computation studies, beginning with the theoretical work of David Marr in the 1970s, suggests that pattern completion depends on the recurrent connections between the CA3 pyramidal cells and that pattern separation depends on the direct projection from the entorhinal cortex to the dentate gyrus. The dentate's role in pattern separation was suggested because the number of granule cells in the dentate far exceeds the number of CA3 or CA1 pyramidal neurons. These ideas have now received support from genetic experiments by Susumu Tonegawa and his colleagues.

The importance of LTP between CA3 neurons is seen in studies performed on mice in which the NMDA glutamate receptor is selectively deleted in the CA3 neurons. These mice experience a selective loss of LTP at the recurrent synapses between CA3 neurons, with no change in LTP at the mossy fiber synapses

onto the CA3 neurons or at the Schaffer collateral synapses between CA3 and CA1 neurons. Despite this deficit, the mice show normal learning and memory in the water maze. However, when the mice are asked to find a hidden platform with fewer than the normal number of spatial cues, their performance is impaired. This indicates that LTP at the recurrent synapses between CA3 neurons is important for pattern completion.

Similarly, the mechanism of pattern separation has been examined in mice in which a critical subunit of the NMDA receptor is selectively deleted from granule neurons in the dentate gyrus, or in which the neural activity of the granule neurons is blocked. Mutant mice lacking a functional NMDA receptor in the dentate gyrus have difficulty distinguishing between two similar contexts—that is, the mice cannot perform pattern separation.

One of the most unexpected findings in neuroscience has been the realization that neurogenesis is not limited to early stages of development. New neurons continue to be born throughout adulthood and become incorporated into neural circuits. However, adult neurogenesis is limited to two types of neurons in two brain regions: inhibitory granule cells in the olfactory bulb and the excitatory granule neurons of the dentate gyrus. When neurogenesis in the dentate is blocked, either by X-ray irradiation of specific brain regions or administration of a chemical that interferes with DNA synthesis, there is a variable effect on learning and memory; some forms of hippocampal-dependent memory are impaired whereas others appear intact. However, recent exciting results show that pattern separation specifically requires the participation of adult-born granule neurons. Moreover, procedures that stimulate neurogenesis enhance the ability of a mouse to perform pattern separation during a contextual memory task, which requires the animal to discriminate between closely related environments. Methods to enhance neurogenesis are now being explored as a means of treating different types of age-related memory loss.

Memory Also Depends on Long-Term Depression of Synaptic Transmission

If synaptic connections could only be enhanced and never attenuated, synaptic transmission might rapidly saturate—the strength of the synaptic connection might reach a point beyond which further enhancement is not possible. Yet individuals are able to learn and store new memories throughout a lifetime. This paradox led to the suggestion that neurons must have mechanisms to downregulate synaptic function to counteract LTP.

In fact such an inhibitory mechanism, termed *long-term depression* (LTD), was first discovered in the cerebellum, where it is important for motor learning. Since then, LTD has also been characterized at a number of synapses within the hippocampus. Whereas LTP is typically induced by a brief, high-frequency tetanus, the induction of LTD requires prolonged periods of low-frequency synaptic stimulation such as stimulation at 1 Hz for 15 minutes. LTD can also be induced by a pairing protocol, in which an EPSP is evoked after a postsynaptic cell fires an action potential. This suggests an anti-Hebbian learning rule: Synapses that do not contribute to the firing of a cell are weakened. Like LTP, a number of molecular and synaptic mechanisms are available to produce LTD.

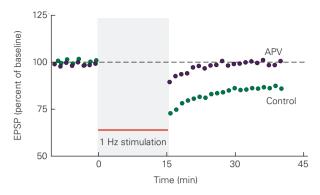

Surprisingly many of the forms of LTD also require activation of the same receptors involved in LTP, namely the NMDA receptors (Figure 67–17A). Moreover, like LTP, LTD is thought to require Ca²⁺ influx through the NMDA receptors into the postsynaptic neuron. How can activation of a single type of receptor leading to elevated levels of a single second messenger, Ca²⁺, produce both potentiation and depression?

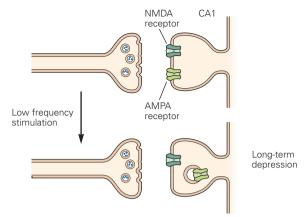

A key difference lies in the protocols used to induce LTP or LTD. Compared to the high-frequency stimulation used to induce LTP, the low-frequency tetanus used to induce LTD produces a relatively modest post-synaptic depolarization and thus is much less effective at relieving the Mg²⁺ block of the NMDA receptors. As a result, the increase in the postsynaptic Ca²⁺ concentration is much smaller than observed during induction of LTP. This low concentration of Ca²⁺ is thought to be insufficient to activate CaMKII, the enzyme implicated in LTP. Rather, LTD is thought to result from the activation of the calcium-dependent phosphatase calcineurin, an enzyme complex that has a higher affinity for Ca²⁺ compared to that of CaMKII (see Chapter 11).

The activated calcineurin triggers a signaling cascade that activates still other phosphatases that dephosphorylate a number of proteins, including the GluA1 (also known as GluR1) subunit of the AMPA receptor. In addition to activating phosphatases, the LTD induction protocol also increases the phosphorylation of the GluA2 (or GluR2) subunit of the AMPA receptor by protein kinase C. The combined effects of dephosphorylation of GluA1 and phosphorylation of GluA2 trigger the endocytosis of the AMPA receptors, reducing the number of receptors in the postsynaptic membrane and thus reducing the size of the EPSP.

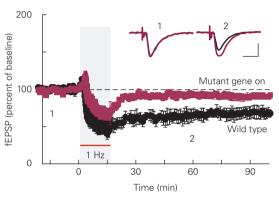

Distinct forms of LTD can be induced through the activation of metabotropic glutamate receptors. Such forms do not require activation of phosphatases but depend on activation of mitogen-activated protein (MAP)

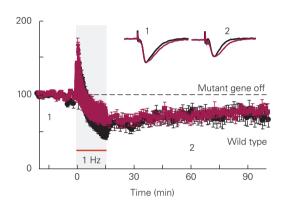

A NMDA receptors are required for long-term depression

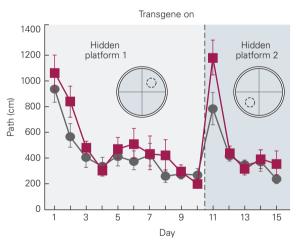

B Protein phosphatase 2A is required for LTD

C LTD contributes to behavioral flexibility

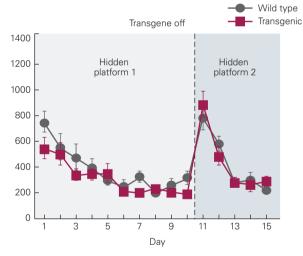

Figure 67–17 Long-term depression of synaptic transmission requires NMDA receptors and phosphatase activity.

A. Prolonged low-frequency stimulation (1 Hz for 15 minutes) of Schaffer collateral fibers produces a long-term decrease in the size of the field EPSP in the hippocampal CA1 region, a decrease that outlasts the period of stimulation (control). The diagram shows that long-term depression (LTD) results from removal of AMPA receptors from the postsynaptic membrane by endocytosis. This LTD is blocked when the 1 Hz stimulation is given in the presence of APV to block NMDA receptors. (Reproduced, with permission, from Dudek and Bear 1992.)

B. Long-term depression requires protein dephosphorylation. The plots compare LTD in the CA1 region of wild-type mice and transgenic mice that express a protein that inhibits phosphoprotein phosphatase 2A. Transgene expression is under control of the tTA system. In the absence of doxycycline, when the

protein inhibitor is expressed, induction of LTD is inhibited (left plot). When inhibitor protein expression is turned off by administering doxycycline, a normal-sized LTD is induced (right plot).

C. Inhibition of phosphatase 2A alters behavioral flexibility. Transgenic mice expressing the phosphatase inhibitor learn the location of the submerged platform in the Morris maze at the same rate as wild-type mice (days 1 through 10). Learning is measured by the daily decrease in the path length the mice traverse as they search for the platform during training. At the end of day 10 the platform is moved to a new hidden location and the mice are retested (days 11–15). Now the transgenic mice require significantly longer path lengths to find the platform on the first day of retesting (day 11). When transgene expression is turned off with doxycycline, the transgenic mice display normal learning on all phases of the test. (Panels B and C reproduced, with permission, from Nicholls et al. 2008.)

kinase signaling pathways (see Chapter 11). These types of LTD lead to a reduction in synaptic transmission through a decrease in glutamate release from the Schaffer collateral terminals as well as through alterations in the trafficking of AMPA receptors in the post-synaptic cells.

Much less is known about the behavioral role of LTD compared to that of LTP, but some insight has come from recent studies using a transgenic mouse that expresses an inhibitor of protein phosphatase under regulated control. This mouse shows a deficit in NMDA receptor-dependent LTD when the transgene is expressed but shows normal LTD when transgene expression is suppressed (Figure 67–17B). In contrast, transgene expression does not affect LTP or forms of LTD that involve metabotropic glutamate receptors. The transgene-expressing mice also show normal learning the first time they are tested in the Morris maze. However, when the mutant mice are retested after the hidden platform has been moved to a new location, they show a decreased ability to learn the new location and tend to persevere in searching for the platform near the previously learned location (Figure 67-17C). This result suggests that LTD is needed for behavioral flexibility. Thus LTD may be necessary not only to prevent LTP saturation, but also as an active participant in memory storage.

Epigenetic Changes in Chromatin Structure Are Important for Long-Term Synaptic Plasticity and Learning and Memory

As is the case with long-term implicit memory, long-term explicit memory storage also requires covalent alterations in chromatin structure. Such changes are termed epigenetic. One form of epigenetic regulation involves acetylation of histone proteins, the protein component of the nucleosome repeat unit of chromatin. CREB binds to the cAMP-recognition element (CRE) promoter and recruits a transcriptional coregulator, the CREB-binding protein (CBP), which functions as a histone acetylase. Acetylation of the N-terminal tails of histones by CBP disrupts repressive chromatin structure and opens up the promoter region of target genes, allowing the binding of RNA polymerase II to initiate transcription (Figure 67–18A).

Mutations in CBP underlie Rubinstein-Taybi syndrome, a rare condition characterized by mental retardation and skeletal abnormalities. Rubinstein-Taybi syndrome can be modeled in mice by insertion of a truncated nonfunctional form of CBP into the mouse genome. These mice show a reduction in histone

acetylation and impairment in the late phase of LTP that is associated with a deficit in certain forms of hippocampal-dependent long-term memory.

Whereas defects in histone acetylation result in memory impairment, enhancement of histone acetylation using inhibitors of histone deacetylase (HDAC) can enhance memory. Remarkably, in a mutant mouse line that undergoes significant hippocampal degeneration, memory capabilities that have been lost following neuronal death can be recovered by treatment of the mice with HDAC inhibitors, raising the possible clinical usefulness of these compounds, which were first developed as anticancer agents.

A second form of chromatin modulation that has been implicated in learning and memory involves DNA methylation (Figure 67-18B). Certain cytosine bases that precede guanine bases in DNA (CpG sites) can be methylated by DNA methyltransferases. DNA methylation recruits methyl-CpG-binding proteins that in turn bind transcriptional corepressor complexes that inhibit gene expression, in part because these complexes contain HDACs. DNA methylation is thought to be of particular importance during early development, when it helps initially to determine cell fate and maintain cell identity. Evidence that DNA methylation is important for proper development of the human nervous system is illustrated by the fact that mutations in the methyl-CpG-binding protein 2 underlie Rett syndrome, a pervasive neurodevelopmental disorder discussed in Chapter 64.

Recent experiments suggest that DNA methylation may also play an acute role in learning and memory in the adult. Thus contextual fear conditioning in mice causes an increase in methylation of the gene encoding the neurotrophin BDNF in the CA1 region of the hippocampus, which leads to changes in BDNF expression. Injection of pharmacological inhibitors of DNA methylation into the CA1 region both inhibits the change in BDNF expression and impairs fear memory 24 hours after conditioning. Consistent with findings for other forms of hippocampal-dependent learning and memory, the changes in DNA methylation require activation of the NMDA receptor. At present the mechanism linking NMDA receptor activation to changes in DNA methylation is unknown.

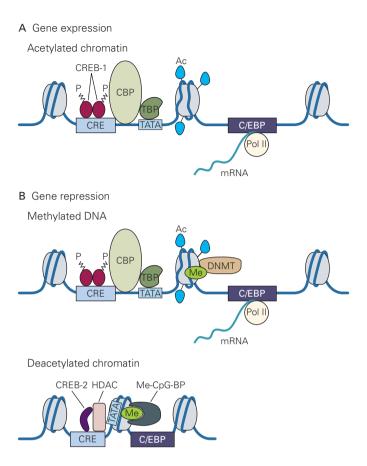

Are There Molecular Building Blocks for Learning?

Three key findings have emerged from cellular studies of implicit and explicit memory storage. First, the molecular mechanisms of some associative forms of

Figure 67–18 Long-term memory requires epigenetic alterations in chromatin structure.

A. Phosphorylation of CREB-1 following induction of the late phase of LTP in the hippocampus recruits the binding of CBP to the promoter region of target genes. In turn CBP acetylates certain positively charged lysine residues on the N-terminal tails of histone proteins, which form the nucleosome unit of chromatin. Acetylation loosens the binding of negatively charged DNA to the histones, allowing transcription to proceed and resulting in the late phase of LTP.

B. The induction of LTP also leads to changes in methylation of certain cytosine bases that precede guanine nucleotides (CpG sites) in DNA through the action of DNA methyltransferases (DNMT). This recruits methyl-CpG-binding proteins (Me-CpG-BP), which in turn recruit histone deacetylases (HDAC), leading to a decrease in histone acetylation, which, together with CREB-2, represses transcription.

synaptic plasticity are based on those of nonassociative forms in the same cell. This suggests that there may be molecular building blocks for synaptic plasticity. Simpler forms of plasticity might serve as components of more complex mechanisms, such as the joint recruitment of presynaptic and postsynaptic mechanisms of plasticity.

Second, the molecular mechanisms of elementary forms of associative learning, both implicit and explicit, are similar. The two synaptic mechanisms for memory storage we have considered—activity-dependent presynaptic facilitation for storing implicit memory and associative long-term potentiation for storing explicit memory—seem to derive from the associative properties of specific proteins (eg, the responsiveness of adenylyl cyclase or the NMDA receptor when two independent signals are simultaneously present).

Finally, despite their clear differences, implicit and explicit memory storage seem to rely on elements of a common multi-component genetic switch involving protein kinase A, CREB, and epigenetic changes in chromatin structure that convert labile short-term

memory into long-term memory. Moreover, these mechanisms of synaptic plasticity do not operate in isolation. Rather, they are embedded in distributed neural circuits that have considerable computational power and thus can add substantial complexity to the actions of individual cells.

An Overall View

The demonstration that changes in the effectiveness of neural connections underlie memory, and thus learning, has revised our view of the relationship between social and biological processes in the shaping of an individual's behavior, both in health and disease. Until recently the majority view in medicine and psychiatry was that biological and social determinants of behavior act on separate components of the mind. For example, psychiatric illnesses were traditionally classified as either organic or functional. Organic mental illnesses included the dementias such as Alzheimer disease and the toxic psychoses such as those that

follow the chronic use of alcohol. Functional mental illnesses included the various depressive syndromes, the schizophrenias, and the neuroses.

This distinction dates to the 19th century when neuropathologists examined the brains of patients coming to autopsy and found gross and readily demonstrable distortions in the architecture of the brain in some psychiatric diseases but not in others. Diseases that produce anatomical evidence of brain lesions were called *organic*; those lacking these features were called *functional*.

This distinction is no longer tenable, as the last two chapters of this book make clear. Everyday events—sensory stimulation, deprivation, and learning—can effectively weaken synaptic connections in some circumstances and strengthen them in others. We no longer think that only certain diseases ("organic diseases") affect mentation through biological changes in the brain whereas others ("functional diseases") do not. The basis of contemporary neural science is that all mental processes are biological and therefore any alteration in those processes is necessarily organic.

The question of the relative roles of nature and nurture in human behavior has shifted. We now ask, how do specific biological processes of the brain give rise to specific mental events and how in turn do social factors modulate the brain's biological structure? In the attempt to understand a particular mental illness it is more appropriate to ask, to what degree is this biological process determined by genetic and developmental factors? To what degree is it determined by a toxic or infectious agent, or by a developmental abnormality? To what degree is it socially determined? Even those mental disturbances that are considered most heavily determined by social factors must have a biological aspect, as it is the activity of the brain that is being modified by experience.

Insofar as social intervention works—whether through psychotherapy, counseling, or the support of family or friends—it must work by acting on the brain and quite likely on the strength of connections between nerve cells. Moreover, the absence of detectable structural changes does not rule out the possibility that important biological changes are nevertheless occurring. They may simply occur at a subcellular or even molecular level that is below the level of detection with the techniques available to us.

Demonstrating the biological nature of mental functioning requires more sophisticated anatomical methodologies than the light-microscopic histology of 19th-century pathologists. To clarify these issues it will be necessary to develop a neuropathology of mental illness that is based on anatomical structure *and* function.

Imaging techniques—positron emission tomography and functional magnetic resonance imaging among others—have allowed the noninvasive exploration of the human brain on a cell-biological level, the level of resolution that is required to understand the physical mechanisms of mentation and therefore of mental disorders. This approach is being pursued in the study of schizophrenia and depression.

In studying the specific cellular changes that underlie memory storage, we should look for altered gene expression in abnormal as well as normal mental states. There is now substantial evidence that the susceptibility to major psychotic illnesses—schizophrenia and bipolar disorder—is heritable. Nevertheless, a sibling whose identical twin develops schizophrenia has only a 50% chance of also developing a psychosis. Thus environmental factors must also be important. The cell-biological data on learning and long-term memory reviewed in this chapter suggest that neurotic illnesses acquired by learning are likely to involve alterations in the *regulation* of gene expression (Figure 67–19).

Development, hormones, stress, and learning are all factors that alter gene expression by modifying the binding of transcriptional regulatory proteins to each other and to the regulatory regions of genes. It is likely that at least some neurotic illnesses (or components of them) result from effects of gene regulation that are reversible. It is intriguing to think, then, that insofar as psychotherapy is successful in changing behavior it does so by producing alterations in gene expression. If so, treatment of neurosis or character disorders by psychotherapeutic intervention would, if successful, also produce structural changes in the nervous system. Thus we face the attractive possibility, for which there is now preliminary evidence, that improved brain imaging techniques might ultimately be useful not only for diagnosing various psychiatric illnesses but also for monitoring the progress of psychotherapy.

When we consider together what we know about synapse formation and synaptic plasticity, it is clear there are two overlapping stages in the development and maintenance of synapses. The first stage, the initial steps of synapse formation, occurs primarily early in development and is under the control of genetic and developmental processes, commonly diffusible signals, cell matrix interactions, and cell-cell interactions. The second stage, the fine tuning of synapses by experience, occurs daily throughout later life. The activity-dependent mechanisms at work during critical periods of development are thought to be closely related to the activity-dependent cellular mechanisms involved in associative learning. Recent evidence indicates that age-related memory loss, including that which occurs

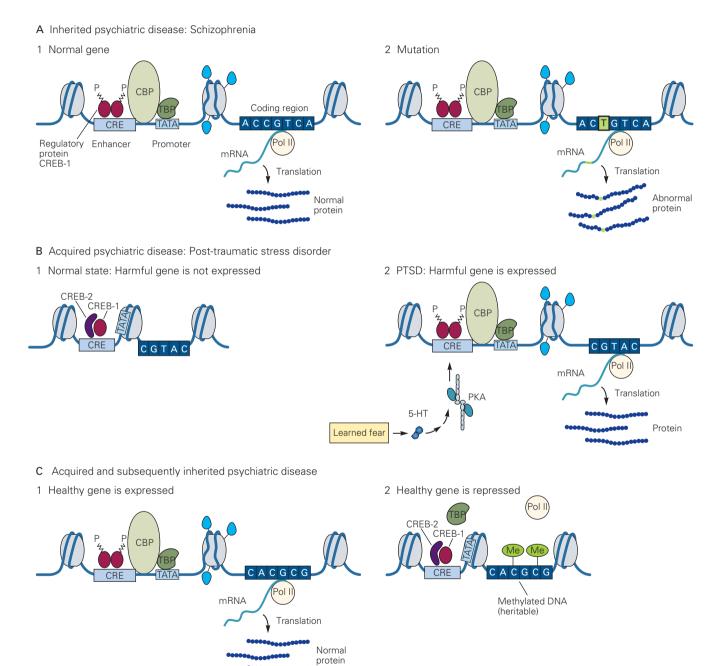

Figure 67–19 (Opposite) Inherited and acquired illnesses both involve genetic changes. Inherited illnesses result from the expression of altered genes, whereas acquired illnesses (neuroses) involve the modulation of normal gene expression by environmental stimuli. The gene illustrated here has two segments. A coding region is transcribed into mRNA by an RNA polymerase and the mRNA in turn is translated into a specific protein. A regulatory segment consists of enhancer and promoter regions (see Box 11–1). In this example the RNA polymerase can transcribe the gene when the regulatory proteins CREB-1 and CBP bind to the enhancer region. For binding to occur, CREB-1 must be phosphorylated (P).

A. Inherited psychiatric disease. 1. Under normal conditions the phosphorylated CREB regulatory protein binds the enhancer segment, thereby activating transcription of the structural gene, leading to the production of the protein. 2. A mutant form of the coding region of the structural gene, for example, in which a thymidine (T) has been substituted for cytosine (C), leads to transcription of an altered messenger RNA. This in turn produces an abnormal protein, giving rise to the disease state. This alteration in gene structure may become established in the germline and therefore heritable.

B. Acquired disease. 1. If the regulatory protein for a normal structural gene is not phosphorylated, it cannot bind the promoter site and thus gene transcription cannot be initiated.

2. A specific frightening experience can lead to the activation of a modulatory transmitter such as serotonin (5-HT), which leads to elevation of cAMP and activation of protein kinase A. The catalytic subunit phosphorylates the regulatory protein, which then can bind to the enhancer segment and thus initiate gene transcription. By this means an abnormal learning experience could lead to the altered expression of a protein that gives rise to symptoms of a psychiatric disorder such as post-traumatic stress disorder.

C. Heritable epigenetic changes. Certain experiences, for example extreme stress during early childhood, can lead to changes in DNA methylation, which alters gene expression. Such changes in methylation can be maintained even during DNA replication as a result of the activity of maintenance DNA methyltransferases. In some instances changes in DNA methylation can be passed from a mother to her offspring.

in the early stages of Alzheimer disease, may primarily result from a defect in synaptic plasticity. Drugs that enhance the ability to induce synaptic plasticity, and in particular LTP, offer a promising approach for the treatment of memory loss.

The finding that epigenetic changes play important roles in learning, memory and behavioral modifications adds a new dimension to our understanding of how environmental and social interactions can produce long-lasting changes in the nervous system. What is particularly striking is that these epigenetic changes allow environmental influences to be passed from a mother onto her offspring. Infant neglect and child abuse are extremely stressful for the developing child and are thought to contribute to cognitive and social deficits that lead to the later development of psychiatric illnesses such as anxiety states and depression.

We now know that early prenatal and postnatal environmental influences, including maternal behavior, can lead to persistent chromatin modifications in the form of direct methylation of the genes that encode hormones, growth factors, and receptors that are important for learning, memory, and emotional states. Moreover, females that experienced maltreatment during infancy later produce offspring that inherit this DNA methylation for at least one generation. Thus, not only our own experience, but that of our mothers, can have a direct and lasting influence on our genetic landscape.

The convergence of neurobiology, cognitive psychology, neurology, and psychiatry that we have emphasized throughout this book is filled with promise. Modern

cognitive psychology has shown that the brain stores an internal representation of the world while neurobiology has shown that this representation can be understood in terms of the activity of individual nerve cells and their interconnections. This synthesis has given us a deeper understanding of perception, learning, and memory as well as profound new biological insight into the nature of mental illnesses.

Connectome of Caenorhabditis elegans. Behavior is determined by the connections between an organism's nerve cells. Networks of neurons, which in mammals reach an astounding degree of complexity, choreograph our simplest reflexes and our most profound insights. While exploration of neural networks in the mammalian brain is in its early stages, the complete set of neural connections—the connectome—has been almost entirely mapped for the nematode C. elegans. With only 302 neurons, 6393 chemical synapses, 890 gap junctions, and 1410 neuromuscular junctions, this simple animal provides a window into the operations carried out by a complete nervous system. In this image each point represents a neuron and the thickness of each line reflects the number of contacts between the neurons (from 1–37). Gap junctions are red, chemical synapses are blue, and neuromuscular junctions are magenta; all neuromuscular junctions are directed at one idealized point in the graph. For simplicity, directionality and neuron type are not shown. (Reproduced, with permission, from Eduardo Izquierdo, with data from White, JG, Southgate E, Thomson JN, Brenner S. 1986. AMILIARITY WITH THE BASIC PRINCIPLES of electrical circuit theory is important for understanding the equivalent circuit model of the neuron developed in Chapters 6, 7, and 9. The appendix is divided into three parts:

- 1. The definition of basic electrical parameters.
- 2. A set of rules for elementary circuit analysis.
- 3. A description of current in circuits with capacitance.

Basic Electrical Parameters

Potential Difference (*V* or *E*)

Electrical charges exert an electrostatic force on other charges: like charges repel, opposite charges attract.

The force decreases as the distance between two charges increases. *Work* is done when two charges that initially are separated are brought together. Negative work is done if their polarities are opposite and positive work if they are the same. The greater the values of the charges and the greater their initial separation, the greater the work done. (Work = $\int_{r_1}^0 f(r) dr$ where f is electrostatic force and r_1 is the initial distance between the two charges.)

Potential difference is a measure of this work: The *potential difference* between two points is the work that must be done to move a unit of positive charge (one coulomb) from one point to the other (ie, it is the potential energy of the charge). One volt (*V*) is the energy required to move one coulomb a distance of one meter against a force of one newton.

Current (I)

A potential difference exists within a system whenever positive and negative charges are separated. Charge separation may be generated by a chemical reaction (as in a battery) or by diffusion of two electrolyte solutions with different ion concentrations across a selectively permeable barrier, such as a cell membrane. If a charge separation exists within a conducting medium, charges move between the areas of potential difference: Positive charges are attracted to the region with a more negative potential, and negative charges to the region of positive potential.

Current is defined as the net movement of charge per unit time. According to convention, the direction of current is defined as the direction of flow of positive charge. In metallic conductors current is carried by negatively charged electrons, which move in the opposite direction of conventionally defined current. In nerve and muscle cells current is carried by both positive and negative ions in solution. One ampere (*A*) of current represents the movement of one coulomb (of charge) per second.

Conductance (g)

Any object through which electrical charges can flow is called a conductor. The unit of electrical conductance is the siemens (*S*). According to Ohm's law the current that flows through a conductor is directly proportional to the potential difference across it:¹

$$I = V \times g$$

Current (A) = Potential difference (V) \times Conductance (S).

As charge carriers move through a conductor, some of their electrical potential energy is converted into thermal energy caused by their frictional interactions with the conducting medium.

Each type of material has an intrinsic property called *conductivity* (σ), which is determined by its molecular structure. Metallic conductors conduct electricity extremely well and thus have high conductivities. Aqueous solutions with high-ionized salt concentrations have somewhat lower conductivity, and lipids have very low conductivity—they are poor conductors of electricity and are therefore good insulators. The conductance of an object is proportional to σ times its cross-sectional area divided by its length:

$$g = (\sigma) \times \text{area/length}.$$

Length is defined as the direction along which one measures conductance. For example, the conductance measured along the cytoplasmic core of an axon is reduced if its length is increased or its diameter decreased (Figure A–1).

Electrical resistance (R) is the reciprocal of conductance and a measure of the resistance provided by an object to current. Resistance is measured in ohms (Ω):

$$1 \Omega = 1/(1 S)$$
.

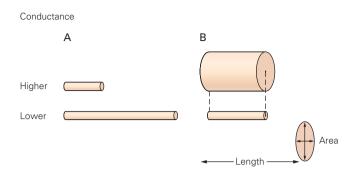

Figure A–1 The conductance of an object is determined by geometric factors, together with conductivity. Conductance is inversely proportional to the length of the conductor (A) and directly proportional to the cross-sectional area of the conductor (B).

Capacitance (C)

A capacitor consists of two conducting plates separated by an insulating layer. Its fundamental property is its ability to separate charges of opposite sign: Positive charges are stored on one plate, negative charges on the other. In the example in Figure A–2 a net excess of positive charges on plate x and an equal excess of negative charges on plate y results in a potential difference between the two plates.

This potential difference can be measured by determining how much work is required to move a positive test charge from y to x. Initially, the test charge is attracted by the negative charges on y and repelled by the more distant positive charges on x. The result of these electrostatic interactions is a force f that opposes the movement of the charge from y to x. However, as the test charge is moved toward x, the attraction by the negative charges on y diminishes and the repulsion by the positive charges on x increases, with the result that the net electrostatic force exerted on the test charge is constant everywhere between x and y. Work (W) is force times the distance (D) over which the force is exerted:

$$W = f \times D$$
.

The work done in moving the test charge from one side of the capacitor to the other is equal to the difference in electrical potential energy, or potential difference, between *x* and *y*. In Figure A–2 it is shown as the shaded region in the plots.

Capacitance is measured in farads (F). The greater the density of charges on the capacitor plates, the greater the force acting on the test charge and the

¹This formula for current flow is analogous to other formulas for describing flow (eg, bulk flow of a liquid caused by a hydrostatic pressure, flow of a solute in response to a concentration gradient, flow of heat in response to a temperature gradient, etc.). In each case flow is proportional to the product of a driving force times a conductance factor.

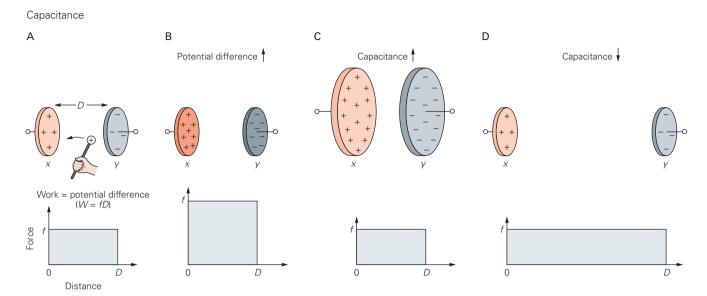

Figure A-2 The capacitance of a parallel-plate capacitor is determined by the area of the two plates and the distance between them.

- **A.** A test charge moved between two charged plates must overcome a force. The work done against this force is the potential difference between the two plates.
- **B.** Increasing the density of charge carriers increases the potential difference.
- **C.** Increasing the area of the plates increases capacitance by increasing the number of charges required to produce a given potential difference.
- **D.** Increasing the distance between the two plates decreases capacitance, decreasing the number of charges required to produce a given potential difference.

greater the resulting potential difference across the capacitor (see Figure A–2B). Thus, for a given capacitor there is a linear relationship between the amount of charge (*Q*) stored on its plates and the potential difference across it:

$$Q$$
 (coulombs) = C (farads) $\times V$ (volts) (A-1)

where *C*, the capacitance, is a constant.

The capacitance of a parallel-plate capacitor is determined by two features of its geometry: the area (*A*) of the two plates and the distance (*D*) between them. Increasing the area of the plates increases capacitance because a greater amount of charge must be deposited on each side to produce the same charge density, which is what determines the force *f* acting on the test charge (Figure A–2A and C). Increasing the distance between the plates does not change the force acting on the test charge, but it does increase the work that must be done to move it from one side of the capacitor to the other (Figure A–2A and D). Therefore, for a given charge separation between the two plates, the potential difference between them is proportional to the distance. Put another way, the greater the distance, the smaller the

amount of charge that must be deposited on the plates to produce a given potential difference, and therefore the smaller the capacitance (Equation A–1).

These geometrical determinants of capacitance can be summarized by the equation

$$C \propto A/D$$
.

As shown in Equation A–1, the separation of positive and negative charges on the two plates of a capacitor results in a potential difference between them. The converse of this statement is also true: The potential difference across a capacitor is determined by the net positive and negative charge on its plates. For the potential across a capacitor to change, the amount of electrical charges stored on the two conducting plates must change first.

Rules for Circuit Analysis

Familiarity with a few basic rules for electric circuit analysis will help in understanding the equivalent circuits used throughout the textbook.

Conductance

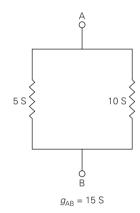

The symbol for a conductor is:

A variable conductor is represented as:

A pathway with infinite conductance (zero resistance) is called a *short circuit* and is represented by a line:

Conductances in parallel add:

Conductances in series add reciprocally:

$$1/g_{AB} = 1/5 + 1/10 = 3/10$$

 $g_{AB} = 3.3$ S.

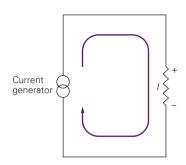

Resistances *in series* add, while resistances *in parallel* add reciprocally.

Current

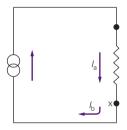

An arrow denotes the direction of current (net movement of positive charge). Ohm's law is

$$I = V \times g = V/R$$
.

When charge flows through a conductor, the end that the current enters is positive with respect to the end that it leaves:

The algebraic sum of all currents entering or leaving a junction is zero. (We arbitrarily define current approaching a junction as positive, and current leaving a junction as negative.) In the following circuit for junction \boldsymbol{x}

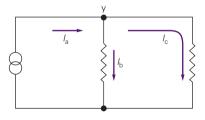

the currents are

$$I_{a} = +5 A$$

$$I_{b} = -5 A$$

$$I_{a} + I_{b} = 0.$$

In the following circuit for junction *y*

the currents are

$$I_a = +3 A$$

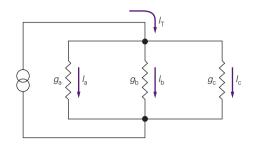

$$I_b = -2 A$$

$$I_c = -1 A$$

$$I_a + I_b + I_c = 0.$$

Current follows the path of greatest conductance (least resistance). For conductance pathways in parallel, the current through each path is proportional to its

conductance value divided by the total conductance of the parallel combination:

$$I_{T} = 10 \text{ A}$$

$$g_{a} = 3 \text{ S}$$

$$g_{b} = 2 \text{ S}$$

$$g_{c} = 5 \text{ S}$$

$$I_{a} = \frac{I_{T} \times g_{a}}{g_{a} + g_{b} + g_{c}} = 3 \text{ A}$$

$$I_{b} = \frac{I_{T} \times g_{b}}{g_{a} + g_{b} + g_{c}} = 2 A$$

$$I_{c} = \frac{I_{T} \times g_{c}}{g_{a} + g_{b} + g_{c}} = 5 \text{ A}.$$

Capacitance

The symbol for a capacitor is:

$$\circ$$

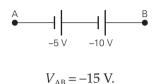

The potential difference across a capacitor is proportional to the charge stored on its plates:

$$V_C = Q/C$$
.

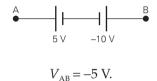

Potential Difference

The symbol for a battery or electromotive force (*E*) is

The positive pole is always represented by the longer bar. Batteries in series add algebraically, but attention must be paid to their polarities. If their polarities are the same, their absolute values add:

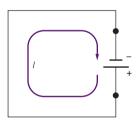

If their polarities are opposite, they subtract:

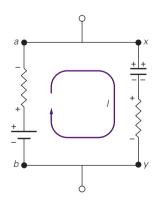

(Here the convention used for potential difference is that $V_{\rm AB} = V_{\rm A} - V_{\rm B}$.)

A battery drives a current around the circuit from its positive to its negative terminal:

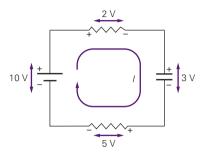

For purposes of calculating the total resistance of a circuit, the internal resistance of a battery is set at zero.

The potential differences across parallel branches of a circuit are equal:

$$V_{\rm ab} = V_{\rm xy}$$
.

As one goes around a closed loop in a circuit, the algebraic sum of all the potential differences is zero:

Thus,

$$2 V + 3 V + 5 V - 10 V = 0$$
.

Current in Circuits with Capacitance

Circuits that have capacitive elements are much more complex than those which have only batteries and conductors because in capacitive circuits current varies with time. The time dependence of changes in current and voltage in capacitive circuits is illustrated qualitatively in the following three examples.

Circuit with Capacitor

Current does not cross the insulating gap in a capacitor; rather, it builds up positive and negative charges on the capacitor plates. However, we can measure a current into and out of the terminal of a capacitor. Consider the circuit shown in Figure A–3A. When switch S is closed, the battery *E* moves a net positive charge onto

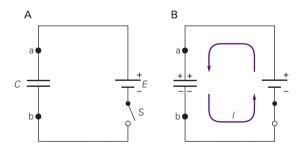

plate a, and an equal amount of net positive charge is withdrawn from plate b. The result is a counterclockwise current in the circuit (Figure A–3B).

Because this current flows into or out of the terminals of a capacitor, it is called a *capacitive current* (I_c). Because there is no resistance in this circuit, the battery E can generate a very large amplitude of current that will charge the capacitance to a value $Q = E \times C$ instantaneously (Figure A–3D).

Circuit with Resistor and Capacitor in Series

Now consider what happens if a resistor is added in series with the capacitor (Figure A–4A). The maximum current that can be generated when switch S is closed (Figure A–4B) is now limited by Ohm's law (I = V/R). Therefore the capacitor charges more slowly. When the potential across the capacitor has finally reached the value $V_c = Q/C = E$ (Figure A–4C), there is no longer a difference in potential around the loop (ie, the battery voltage E is equal and opposite to the voltage across the capacitor, V_c). The two thus cancel out, and no net potential difference is left to drive a current around the loop.

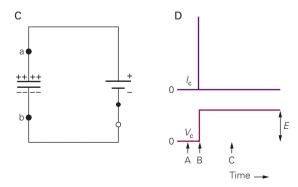

The potential difference is greatest, and current is at a maximum, immediately after the switch is closed. As the capacitor begins to charge, the net potential difference ($V_c + E$) available to drive a current becomes smaller and current decreases. This results in an exponential change in voltage as well as current across the resistor and the capacitor. Note that in this circuit resistive current must equal capacitative current at all times (see earlier section, Rules for Circuit Analysis).

A. Circuit before the switch (S) is closed.

B. After the switch is closed.

C. After the capacitor has become fully charged.

D. Time course of changes in current (I_c) and potential difference across the capacitor (V_c) in response to closing of the switch.

Figure A–4 Time course of charging a capacitor (*C*) in series with a resistor (*R*) from a constant voltage source (*E*).

- A. Circuit before the switch (S) is closed.
- B. Shortly after the switch is closed.
- **C.** After the capacitor has settled at its final potential.
- **D.** Time course of changes in current (*I*), charge deposited on the capacitor (Q_c), and potential differences across the resistor (V_R) and capacitor (V_c) after closing the switch.

value.

parallel with a resistor (*R*) from a constant current source.

A. Circuit before the switch (S) is

Current generator $I_{max} = I_{T}$ B $I_{max} = I_{T}$ $I_{max} = I_{T}$

Circuit with Resistor and Capacitor in Parallel

Consider now what happens if we place a parallel resistor and capacitor in series with a constant-current generator that generates a total current $I_{\rm T}$ (Figure A–5A). When the switch (S) is closed, charge starts to flow around the loop (Figure A–5B). In the first instant of time after the current begins to flow, all the charge flows into the capacitor (ie, $I_{\rm T} = I_{\rm c}$). However, as charge builds up on the plates of the capacitor, a potential difference $V_{\rm c}$ is generated.

Because the resistor and capacitor are in parallel, the potential across them must be equal; thus part of the total current begins to flow through the resistor, such that $I_{\rm R} \times R = V_{\rm R} = V_{\rm c}$. As less and less charge flows into the capacitor, the rate of charging slows; this accounts for the exponential shape of the curve of voltage versus time. Eventually, the voltage reaches a plateau and no longer changes. When this occurs, all the charge flows through the resistor and $V_{\rm c} = V_{\rm R} = I_{\rm T} \times R$ (Figure A–5C).

Motor Coordination

Gait and Stance

Balance

Deep Tendon Reflexes

THE KEY TO THE ANALYSIS OF SIGNS and symptoms referable to the nervous system is a rigorous neurological examination of the patient. This

examination begins with an assessment of the patient's mental functioning.

Mental Status

Alertness and Attentiveness

A patient's level of consciousness is defined in terms of responses to stimuli. Rather than simply using terms such as *lethargy*, *obtundation*, *stupor*, and *coma*, the examiner needs to note the minimal stimulus that elicits a response (eg, voice, shaking the patient, applying pain) and the response (eg, sustained alertness vs. fleeting eye opening with mumbling).

An impaired attention span is usually apparent during history taking. It can be tested more formally by having the patient repeat a series of numbers or count backward from 20. Sequential digit testing is sensitive, but the test is not specific; difficulty may connote impairment of immediate (working) memory.

Inattentiveness so severe that meaningful interaction with the environment is impossible is characteristic of *delirium*. Such patients are often agitated.

Behavior, Mood, and Thought

Neuropsychiatric abnormalities can be identified in this part of the mental status examination. Affect, the outward expression of mood, may be manifested in clothing, facial expression, amount and type of activity, and stream of conversation. If depression is suspected, the patient should be specifically queried; mood may be more disturbed than affect suggests.

Schizophrenic patients may demonstrate indifference, flattening of affect, or inappropriate mood. They may appear hostile and paranoid. Behavior sometimes suggests hallucinations even when they are denied. Schizophrenic speech may reveal loosening of associations, incoherence, blocking, stereotypy, or distractibility.

Slowing of speech and activity is a manifestation of medial frontal lobe damage (abulia). Lesions of the frontal lobe also produce social disinhibition, inappropriate jocularity, and difficulty sustaining goal-directed behavior.

Orientation and Memory

People aware of their own identity as well as of the basic facts of their surroundings (hospital, home address, city, state; time of day, day of week, month, year) are said to be "oriented to person, place, and time." Memory impairment secondary to brain injury or a dementing illness is usually greater for recent than remote events; such patients are disoriented to place and time but not to person. Disorientation is neither a sensitive nor a specific marker of amnesia, however.

Memory is clinically categorized as immediate (working), recent, and remote. A sensitive test for recent memory is to have the patient repeat three unrelated words (eg, Chicago, orange, thirty-three) and then repeat them after 5 minutes. If unable to recall the words, the patient is asked to select the words from a list. Amnestic disorders tend to affect recall more than recognition. Long-term memory can be tested by having the patient recall people or events from the past and then verifying the answers.

Conventional testing identifies disturbances of explicit memory (see Chapter 67). Amnestic or dementing illnesses are less likely to affect implicit memory systems such as procedural memory (remembering how to perform a skilled motor act).

Cognitive Abilities

Intellectual skills are assessed in standardized IQ tests, which are subject to educational and cultural bias. Tests include calculation, word similarities, word opposites, and proverb interpretation.

Language Disorders

Aphasia is a disturbance of language unexplained by an impairment of the neural machinery for hearing, vision, or vocalizing (see Chapter 60). Clinical subtypes of aphasia can be identified by assessing six basic components of language: spontaneous speech, speech comprehension, naming, repetition, writing, and reading (Figure B–1).

Spontaneous Speech

The patient's speech may be abnormal in a number of ways. *Fluency*, the amount of speech produced over time, may be reduced. *Prosody*, the musical qualities of speech (pitch, accent, rhythm), can also be impaired. In *paraphasias* incorrect words are substituted for correct ones. Patients with *literal* (or phonemic) paraphasia use words that phonetically resemble the intended word but contain one or more substituted syllables (eg, "hosicle" instead of "hospital"). Those with *verbal* (or semantic) paraphasia use real but unintended words (eg, "hotel" instead of "hospital"). In some patients paraphasic errors are simply occasional contaminants of speech; in others, they almost entirely replace it.

Even in the absence of paraphasias the content of aphasic speech may be difficult to grasp. Severely restricted vocabulary may be reflected by logorrheic but empty speech as well as by hesitation before certain words. *Paragrammatic* speech preserves some semblance of syntax despite such profoundly restricted semantic content. By contrast, *agrammatic* (or telegrammatic) speech omits relational words (such as prepositions or conjunctions).

Speech Comprehension

Casual conversation with the patient may not reveal abnormalities of speech comprehension, which can be mild, moderate, or severe. Specific testing is required. Assessment of speech comprehension should not depend on the patient's verbal responses to commands or questions. A wrong answer to a question could signify a paraphasic error rather than failure of comprehension. If a simple or complex command is followed, it can be presumed that the command was understood. However, failure to follow a command could have explanations other than impaired comprehension, for example, paralysis, apraxia, pain, or negativism.

A more reliable method of testing speech comprehension is to ask yes-or-no questions. Even patients with severely restricted speech output can usually indicate affirmative or negative. Both the patient and the examiner must of course know the correct answers. Still another way of testing speech comprehension is to ask the patient to point to objects or body parts.

As with abnormal speech output, semantic and syntactic (relational) comprehension can be dissociated. Syntactic comprehension can be assessed by asking the patient to handle objects. For example, after identifying a comb, a pen, and a key, ask the patient to put the key *on top* of the comb or the comb *between* the key and the pen.

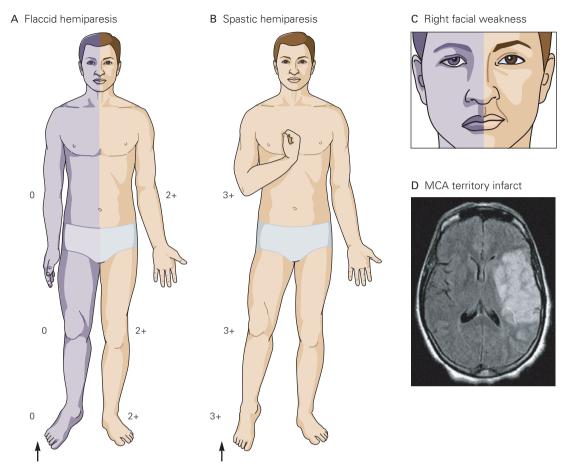

Figure B-1 A stroke in the left middle cerebral artery (MCA) territory producing contralateral hemiparesis and aphasia.

A. The patient develops sudden right-sided weakness involving face, arm, and leg. Examination reveals left gaze preference and weakness of extensor muscles of the right arm, more pronounced distally than proximally, and to a lesser degree weakness of flexors of the right leg. In the first few days tendon reflexes may be absent at the right triceps, knee, and ankle. A right Babinski reflex is present (arrow). Numbers indicate the strength of the reflex, where 2+ is normal. (See the section on Deep Tendon Reflexes.)

B. In weeks to months the patient may develop tonic flexure posture of the right arm and extensor posture of the right leg. Tendon reflexes on the right will become brisk with a positive Babinski reflex.

C. There is weakness of the right side of the face, characterized by widening of the palpebral fissure because of a lax lower lid, blunting of the right nasolabial fold, and drooping of the right corner of the mouth. There may also be acute weakness of the forehead with decreased furrowing of the brow, but this usually resolves quickly as the upper facial motor neurons receive bilateral supranuclear innervation. The patient has a nonfluent aphasia. Speech is effortful and telegraphic, and the prosody is abnormal. The patient cannot repeat words or phrases and becomes easily frustrated but can follow simple commands.

D. Site of stroke is on the left parieto-frontal region. Note that the left is shown on the right in diagnostic brain scans.

Naming

Patients with adequate vision can be shown objects, body parts, colors, or pictures of actions (confrontation naming). A variety of abnormal responses indicate anomia, the loss of the ability to recall or recognize the names of things. Some patients exhibit paraphasias. Some hesitate and grope for the correct word (tip-of-the-tongue phenomenon). Some patients describe

rather than name an object. For example, instead of saying "necktie," the patient says, "It's what you wear around your neck."

Repetition

The patient is asked to repeat sentences such as "In the winter the President lives in Washington." Syntactically

complex sentences may be particularly difficult (for example, "If he were to come, I would go out"). Errors most often consist of paraphasic substitutions.

Writing

Testing of writing begins by having patients sign their names. More specific tests of writing include dictated sentences, words, or letters, as well as spontaneous writing; for example, describing what is seen in a room.

Reading

Reading ability is tested by having the patient read aloud simple sentences, words, or letters. Reading comprehension can be tested by having the patient follow written commands that were previously successfully executed as oral commands or by having the patient answer written yes-or-no questions.

Praxis

Praxis refers to performance of a learned motor act. In its broadest sense apraxia refers to impaired motor activity not explained by weakness, incoordination, abnormal tone, bradykinesia, movement disorder, dementia, aphasia, or poor cooperation. Failure to perform an act is not evidence of apraxia. To be apractic the act must be performed incorrectly, or components of the act must be performed imprecisely. Parts of the act might be omitted, sequenced abnormally, or incorrectly oriented in space. There are three types of testing: (1) gesture ("Show me how you would throw a ball"); (2) imitation ("Watch how I point upward, then you do it"); and (3) use of an actual object ("Here is a spoon. Show me how you would use it").

Apraxias are traditionally classified as limb-kinetic, ideational, and ideomotor. With limb-kinetic apraxia the act is understood but motor execution is faulty. With ideational apraxia the idea of the act—the neural representation of the act, or <code>engram</code>—is disrupted. With ideomotor apraxia the idea of the act and the motor components of its execution are functionally disconnected. Such patients might be unable to imitate using a hammer but able to accurately describe its use and, if given a hammer, use it correctly.

Gnosia and Spatial Manipulation

Agnosia is a failure of recognition not explained by impaired primary sensation (tactile, visual, auditory) or cognitive impairment. It has been described as "perception stripped of its meaning." Agnosia differs from

anomia in that the patient not only fails to name an object but also cannot select it from a group or match it to a picture. With tactile agnosia (astereognosis), touch threshold is normal yet patients cannot identify what they are touching.

Comparable agnosias exist in the visual and auditory spheres. However, because the responsible lesions are likely to be bilateral, visual and auditory agnosias are rare. *Simultanagnosia* is the inability to recognize the meaning of a whole scene or object, even though its individual components are correctly recognized.

The left hemisphere usually processes language and the right hemisphere processes spatial information. Right hemispheric (particularly parietal) lesions impair spatial perception and manipulation; patients have difficulty reading maps or finding their way about (topographagnosia), or difficulty copying simple pictures or shapes or drawing simple objects such as a flower or a clock face (constructional apraxia or apractagnosia).

Even more striking is spatial hemineglect syndrome. Patients with damage to the right hemisphere may ignore objects to the left of midline, including the left side of the body (personal neglect syndrome). They may fail to recognize severe hemiplegia (anosognosia) or even to acknowledge left body parts as their own (asomatognosia). Asked to bisect a line, such patients indicate a point to the right of midline. A copied picture might be missing the left half, and a drawn clock face might have all the numbers neatly arranged on the right.

A subtle manifestation of spatial neglect is *extinction*. Patients are able to recognize a stimulus (visual, auditory, or tactile) on either side when it is presented alone but unable to recognize the stimulus when it is presented on one side while the opposite side is also stimulated.

Cranial Nerve Function

Several of the cranial nerves are multifunctional; their motor, sensory, and autonomic functions must be assessed separately. The optic nerve is actually a central nervous system tract, and the accessory nerve is anatomically an aberrant spinal nerve (the motor neurons reside in the upper spinal cord).

Olfactory Nerve (Cranial N. I)

When patients complain that foods no longer taste right, the first step is to look into the nose for possible obstruction of airflow. Each nostril is then tested separately, using non-noxious odorants such as coffee or soap. (Pungent substances such as ammonia will stimulate trigeminal nociceptors.) Failure to smell anything is termed *anosmia*. Unpleasant distortion of an innocuous odorant is termed *parosmia*.

There are several cerebral representations for olfaction in the brain. As a result anosmia is most often secondary to local nasal disease, or to lesions affecting olfactory fibers as they pass through the cribriform plate (see Figure 32–1).

Optic Nerve (Cranial N. II)

Visual Acuity

Visual acuity is tested with Snellen's chart (at 20 feet) or a hand-held card (at 14 inches). The eyes are tested separately; if acuity is severely reduced, finger counting, detection of hand movement, or light perception should be assessed. Refractive errors are identified by having patients wear their glasses or look through a pinhole. Inspection of the eyes and funduscopic examination will often identify ocular lesions impairing acuity, such as corneal scarring, cataracts, glaucoma, diabetic retinopathy, or macular degeneration.

Visual Fields

The eyes are tested separately. The examiner faces the patient and holds an object equidistant between the patient's and the examiner's eyes to compare his or her own experience with that of the patient. A test object is moved slowly inward from the periphery, and the patient is asked to indicate when it is first seen; or the patient can be told to count fingers in different visual quadrants. Stimuli are presented simultaneously to the right and left fields to identify spatial neglect (extinction).

Visual field testing provides very accurate localization of structural lesions (see Figure 25–5). Monocular visual impairment, including either field defect or scotoma (an area of visual loss surrounded by preserved vision), localizes a lesion to the optic nerve, the retina, or other ocular structures. Bitemporal hemianopia, if caused by a single lesion, places that lesion at the optic chiasm. Homonymous hemianopia, quadrantanopia, or bilateral congruent scotomas indicate a lesion behind the chiasm in the contralateral optic tract, lateral geniculate nucleus of the thalamus, optic radiation, or primary visual cortex.

Funduscopy

Using an ophthalmoscope, the examiner focuses successively on the cornea, anterior chamber, lens, and

vitreous body, and then surveys the optic disk, retinal vessels, and the retina itself. Optic atrophy refers to disk pallor; its many causes include glaucoma, optic nerve compression, infarction, and multiple sclerosis.

In papilledema (optic disk swelling) the disk margins become blurred and elevated. Papilledema can be the result of local pathology, for example the inflammatory demyelination of optic neuritis, in which case visual acuity is acutely impaired by swelling of the optic nerve head. When papilledema is the result of increased intracranial pressure, the normal blind spot becomes enlarged but visual acuity is not initially affected; over time, however, the visual fields become constricted and visual acuity is impaired. In addition, the ratio of the diameter of retinal veins to arteries (normally approximately 3:2) increases, and there may be retinal hemorrhages and whitish exudates.

Other abnormalities identified by funduscopy include arterial narrowing (hypertension), exudates (diabetes mellitus, blood dyscrasias), microaneurysms (diabetes mellitus), subhyaloid hemorrhages (located between the retina and the vitreous membrane and associated with subarachnoid hemorrhage), tubercles and other granulomas, phakomas (glial collections, associated with the hereditary diseases neurofibromatosis and tuberous sclerosis), pigmentary changes (retinitis pigmentosa), and emboli (seen within arteriolar branches of the central retinal artery).

Oculomotor, Trochlear, and Abducens Nerves (Cranial N. III, IV, VI)

Pupils

The pupillary light reflex is tested by directing a bright light into each eye and observing the bilateral response. Both pupils should constrict to bright light in either eye. The accommodation reflex and pupillary near response are tested by having the patient converge onto an object held close to the eyes; the pupils should constrict.

Anisocoria (unequal pupils) signifies either a parasympathetic lesion affecting the larger pupil or a sympathetic lesion affecting the smaller pupil. A parasympathetic lesion is indicated by marked pupillary dilatation, loss of the light reflex, or both, as well as involvement of extraocular muscles innervated by the oculomotor nerve. A sympathetic lesion is indicated by pupillary constriction, preservation of the light reflex, and signs of Horner syndrome (ptosis and, in some cases, loss of sweating over the ipsilateral face). A pupil

with both parasympathetic and sympathetic denervation will be mid-position and unreactive to light.

A unilateral lesion involving the optic nerve or retina is indicated when neither pupil constricts in response to light directed into the affected eye, but both pupils constrict when light is directed into the unaffected eye (afferent pupillary defect). The pupils react equally because the pupillary light reflex is consensual (Figure B–2A; and see Figure 45–7).

The afferent end of the accommodation reflex pathway is in visual areas of the occipital lobe, which communicate with the parasympathetic component (the Edinger-Westphal nucleus) of the oculomotor nucleus by a route separate from the light reflex pathway. Lesions that selectively interrupt the light reflex pathway (for example, Argyll-Robertson pupils, seen most often with neurosyphilis) destroy the light reflex but do not impair the accommodation reflex.

Extraocular Eye Movement

The examiner looks for (1) paresis producing conjugate limitation of gaze in a particular direction (both eyes are equally affected so there is no diplopia); (2) paresis affecting one or more extraocular muscles (producing disconjugate eye movements with diplopia); and (3) spontaneous involuntary eye movements (eg, nystagmus).

The patient is asked to look to the right, to the left, and up and down in each horizontal direction. When the eyes follow a moving target they move more slowly (pursuit velocity) than when shifting from one static object to another (saccadic velocity). The two types of movement are controlled by separate anatomical and physiological mechanisms that can be selectively affected by lesions of the cerebrum, brain stem, or cerebellum (see Figures 39–2, 39–9, and 39–14).

Horizontal gaze palsy usually indicates a lesion of the frontal eye field (FEF) or the pontine paramedian reticular formation (PPRF) (see Figures 39–6, 39–9, and 39–10). If the FEF is affected the eyes will be deviated toward the side of the lesion. If the PPRF is affected the eyes will be deviated away from the side of the lesion.

Vertical gaze paresis—limitation of conjugate upward and downward gaze—indicates damage to the midbrain, either the rostral interstitial nucleus of the median longitudinal fasciculus or the posterior commissure.

Monocular limitation of adduction with preserved convergence (internuclear ophthalmoplegia) indicates damage to the ipsilateral median longitudinal fasciculus. There is often horizontal nystagmus in the contralateral abducting eye (see Figure B–2).

Disconjugate eye movements indicate impairment of particular cranial nerves or extraocular muscles (see Figures 39–4, 39–5, 39–6, and 39–7). If the eye cannot move outward there is a lesion involving either the abducens nerve (N. VI) or the lateral rectus muscle. If the eye cannot move downward when deviated inward there is a lesion of the trochlear nerve (N. IV) or the superior oblique muscle. Any other monocular limitations in movement are caused by a lesion of the oculomotor nerve (N. III) or one of its muscles of innervation (an exception is internuclear ophthalmoplegia).

The oculomotor nerve controls the levator palpebrae muscle, and ptosis is a common sign of lesions of this nerve. Unlike the mild Horner syndrome, oculomotor denervation can result in total eye closure.

The oblique muscles mediate intorsion and extorsion when the eye is either in mid-position or abducted. A compensatory head tilt (away from the side of the lesion) is therefore a feature of trochlear nerve palsy.

Nystagmus

Involuntary repetitive eye movements, or nystagmus, can be either unilateral or bilateral. Pendular nystagmus, with roughly equal velocity in either direction, is most often the result of severe visual impairment during early childhood. Rhythmical nystagmus, a slow drift in one direction followed by a rapid corrective movement in the other, can be present with the eyes at rest and the gaze fixed; it tends to be accentuated by ocular deviation, with the fast component in the direction of gaze.

Horizontal or rotatory nystagmus on primary gaze is most often associated with vestibular lesions, peripheral or central. Vertical nystagmus (the fast component directed upward or downward) suggests a brain stem lesion. Horizontally directed nystagmus on lateral gaze is often a benign side effect of certain drugs, particularly sedatives and anticonvulsants.

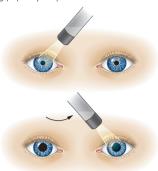

Trigeminal Nerve (Cranial N. V)

The three divisions of the trigeminal nerve carry sensation from the face, anterior scalp, eye, and much of the nasal and oral cavities. Fibers in the mandibular division innervate the muscles of mastication (see Figures 45–2 and 45–3).

The examiner initially checks sensations at the forehead, the malar region, and the chin, defining the outer borders of any deficit found. Decreased sensation confined to the entire trigeminal area indicates a peripheral lesion involving the nerve root or the trigeminal ganglion. Decreased sensation confined to

C Additional signs

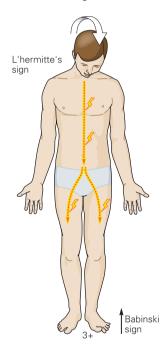

Figure B–2 Multiple sclerosis produces protean symptoms that wax and wane.

A. A common early symptom of multiple sclerosis (MS) is transient blurred vision in one eye as a result of optic neuritis, inflammation of the optic nerve that occurs during the acute phase of an MS lesion. 1. Shining a light in the normal eye produces both direct and consensual pupillary constriction, but when the light is swung to the affected eye, both pupils dilate because the patient perceives a relative dimming of light intensity. This is referred to as a de-afferented pupil. At no time with a de-afferented pupil is there anisocoria. A positive "swinging flashlight test" indicates a de-afferented pupil. 2. To determine the site of the lesion the examiner must use an ophthalmoscope to evaluate the possibility of a corneal or lenticular opacity, vitreous hemorrhage, retinal detachment, or ischemic retinopathy. 3. If the funduscopic examination is normal, or reveals a slight elevation or blurring of the optic nerve head, the lesion is localized to the visual pathway behind the eye. Lack of a homonymous visual field defect involving the other eye localizes the lesion proximal to the optic chiasm, therefore placing the lesion in the retrobulbar segment of the optic nerve consistent with the diagnosis of optic neuritis.

B. The condition known as internuclear ophthalmoplegia (INO) is frequently the result of MS. The patient complains of double

vision. 1. The patient attempts to visually follow a finger moving from side to side. The abducting eye follows but the adducting eye fails to track past the midline. The abducting eye may demonstrate nystagmus. The possibility of a lesion involving the oculomotor nucleus (N. III) is tested by examining convergence. The patient looks at the target finger placed directly in front and follows as the finger is brought toward the patient's nose. Normal adduction during convergence rules out a lesion of the nerve or nucleus. Additionally, the pupils will be observed to constrict as a result of the near response. 2. INO indicates a lesion of the medial longitudinal fasciculus (MLF), the white matter tract that links the third nerve (oculomotor) nucleus in the midbrain with the sixth nerve (abducens) nucleus in the pons to coordinate lateral gaze. Because these tracts are crossed and near the midline, most cases of INO are bilateral.

C. As the result of an MS plaque involving the posterior columns of the cervical cord, patients may experience an electric shock-like sensation traveling down the spine and possibly into the limbs when the examiner flexes the neck (L'hermitte sign). Because MS is a disease of central white matter, lesions may cause upper motor neuron signs, such as brisk reflexes or a Babinski sign.

one division suggests a more distal lesion. If pain and temperature are decreased, but touch is preserved, the lesion involves the spinal trigeminal tract and nucleus in the lower brain stem or upper cervical cord. If touch is also impaired, the lesion involves the principal trigeminal nucleus in the pons. If impaired sensation extends beyond the borders of the trigeminal area, the lesion is suprasegmental in the upper brain stem, thalamus, or parietal lobe.

Because the corneal reflex is consensual (the efferent end of the reflex pathway is in the facial nerve), a purely trigeminal lesion results in a decreased response in both eyes when the affected side is stimulated and a normal response in both eyes when the unaffected side is stimulated. Unilateral weakness of eye closure occurs in the affected eye when either cornea is stimulated.

Unilateral lesions of the trigeminal nerve or its third division cause the opened jaw to deviate toward the ipsilateral side because of ipsilateral pterygoid muscle weakness. Unilateral suprasegmental lesions are unlikely to cause jaw deviation because motor neurons of the trigeminal motor nucleus receive bilateral innervation from the primary motor cortex.

The jaw jerk is produced by tapping downward on the chin when the jaw is slightly open. Like other tendon reflexes it is decreased or absent with lesions of the nuclear or peripheral nerve (lower motor neurons) and brisk with lesions of the corticobulbar tract or motor cortex (upper motor neurons).

Facial Nerve (Cranial N. VII)

The facial nerve supplies facial muscles, including the frontalis ("wrinkle your forehead"), orbicularis oculi ("close your eyes tightly"), orbicularis oris ("close your lips tightly"), levator anguli oris ("show your teeth"), and platysma ("show your teeth and grimace"). With mild lesions there may not be frank weakness but rather a wider opening between the upper and lower eyelids and a flattening of the nasolabial fold ipsilaterally.

More proximal lesions can involve (1) a branch to the stapedius muscle of the middle ear (resulting in an increased sensitivity to loud sounds, or hyperacusis), (2) the chorda tympani branch to the sublingual and submandibular salivary glands and the tongue (resulting in decreased taste over the tongue's anterior two-thirds, usually tested with sugar or salt), or (3) the greater petrosal branch to the lacrimal gland and nasal mucosa (resulting in decreased lacrimation).

In most people motor neurons innervating the upper facial muscles, particularly the frontal muscle, receive projections from the motor cortex of both hemispheres, whereas those innervating the lower facial muscles receive only contralateral projections. Thus suprasegmental lesions tend to spare the frontal muscle and sometimes eye closure (upper-motorneuron facial weakness), whereas lower brain stem or nerve damage tends to involve all the facial muscles (lower-motor-neuron facial weakness).

Following peripheral nerve injury such as Bell's palsy or trauma, aberrant reinnervation may produce synkinesis of the eye and mouth. Eye closure results in involuntary elevation of the angle of the mouth on the affected side, whereas baring the teeth results in involuntary closure of the ipsilateral eye.

Vestibulocochlear Nerve (Cranial N. VIII)

The auditory and vestibular nerves run together as the eighth cranial nerve. Both carry information from the labyrinths of the inner ear. The auditory (cochlear) nerve conveys sound information from the cochlea, whereas the vestibular nerve conveys equilibrium information from the utricle, saccule, and semicircular canals (see Figure 40–1).

Auditory Function

Neurons in the cochlear nucleus project both ipsilaterally and contralaterally. Thus unilateral deafness signifies a lesion of the cochlear nucleus, the auditory nerve, or the ear. Deafness from peripheral lesions is of two types. *Conduction deafness* is the result of obstruction or disease of the external auditory canal, the tympanic membrane, or the middle ear. *Sensorineural deafness* is the result of damage to the cochlea, the cochlear nerve, or the cochlear nuclei. Conduction deafness preferentially affects low tones; sensorineural deafness preferentially affects high tones. Patients with cochlear nerve or cochlear nucleus lesions may have only mildly impaired hearing for pure tones yet severe difficulty in discriminating speech because of its tonal complexity. Both peripheral and central lesions cause tinnitus.

The auditory examination begins with a simple screening test in which the ability of each ear to detect a watch ticking or two fingers rubbed together is compared. The Weber and Rinne tests help to distinguish conduction from sensorineural deafness. In the Weber test a 512 Hz tuning fork is placed midline on the forehead. With conduction deafness the sound will be heard best on the hearing-impaired side, whereas with sensorineural deafness the sound will be heard best on the normal side. In the Rinne test the tuning fork is placed over the mastoid; when the patient reports that the sound is no longer heard, it is held close to the

external auditory meatus. In normal subjects and in those with nerve deafness air conduction will outlast bone conduction. With conduction deafness bone conduction will outlast air conduction. The Weber test is most useful when deafness is unilateral and the Rinne test when deafness is bilateral.

Vestibular Function

The vestibular nerve carries impulses from hair cells in the semicircular canals to the vestibular nuclei in the brain stem. Widespread projections from the vestibular nuclei communicate with the spinal cord, the cerebellum, eye movement control centers, and the forebrain.

Tests of vestibular function involve labyrinthine stimulation, either by head movement, head positioning, or temperature. In some patients vertigo, nystagmus, and sometimes nausea and vomiting are precipitated by any rapid movement of the head. In others, particularly those with benign positional vertigo, vertigo is triggered (after a latency of up to half a minute) by lying on the affected ear.

In the caloric test the ear is irrigated alternately with water several degrees centigrade above and below body temperature. With the head elevated 30 degrees the normal response consists of nystagmus (and vertigo), with the fast component directed away from the cold stimulus but toward the warm stimulus. There are two main patterns of abnormal response. Nystagmus may be absent or briefer in response to a cold or warm stimulus in the same ear; this *canal paresis* is associated with peripheral vestibular lesions. Conversely, a reduced response may occur when cold water is instilled into one ear or warm water is instilled into the other ear; this *directional preponderance* is associated with lesions of central vestibular pathways.

When pointing to objects, vertiginous patients whose eyes are closed tend to deviate toward the side of the lesion (*past-pointing*). Similarly, when walking in place with closed eyes, they tend to rotate toward the affected side.

Glossopharyngeal and Vagus Nerves (Cranial N. IX, X)

Assessment of the ninth and tenth cranial nerves is usually limited to examination of the palate and pharynx. Nasal speech suggests palatal weakness. Hoarseness or a reduced cough suggests laryngeal weakness.

Choking on saliva while talking suggests pharyngeal weakness. Difficulty swallowing (dysphagia) solid food suggests mechanical obstruction such as esophageal carcinoma; dysphagia for liquids as well

as solids or for only liquids suggests neurological dysfunction. Dysphagia can be checked by asking the patient to swallow a small amount of water.

When the patient says, "ah" with the mouth open and the tongue relaxed, the palate should rise symmetrically, the uvula should remain in the midline, and the pharyngeal walls should contract symmetrically. With unilateral palatal or pharyngeal weakness, phonation causes the uvula to deviate toward the normal side. The gag reflex is tested by gently touching each side of the pharynx with a cotton-tipped applicator. As with the pupillary and corneal reflexes, the response is bilateral. The response of the palatal and pharyngeal muscles to phonation and tactile stimulation therefore reveals whether a lesion is unilateral or bilateral, and whether the damaged nerves are efferent, afferent, or both.

With unilateral laryngeal lesions the abnormal vocal cord may be positioned in adduction, in which case there may be no symptoms; if it is positioned in abduction there will be hoarseness or aphonia but normal breathing. With bilateral lesions the vocal cords may be positioned in abduction, in which case there will be hoarseness or aphonia but normal breathing; if they are positioned in adduction there will be inspiratory phonation (stridor) and life-threatening respiratory obstruction.

Spinal Accessory Nerve

The sternocleidomastoid is the only major striated muscle with ipsilateral cortical representation. Following destructive cerebral lesions weakness in the sternocleidomastoid is unusual but may occur ipsilaterally; contralateral trapezius weakness may also occur. The sternocleidomastoid is tested by having patients press their chin against resistance in the direction of the contralateral shoulder. Bilateral damage causes weakness of forward head flexion. Trapezius weakness is demonstrated by assessing shoulder elevation or shrugging or by observing winging of the upper scapula.

Hypoglossal Nerve (Cranial N. XII)

The hypoglossal nerve innervates the muscles of the tongue. It arises near the midline of the medulla oblongata and exits the posterior fossa through the hypoglossal foramen. Each hypoglossal nucleus receives bilateral projections from the motor cortex.

Inspection of the tongue may reveal atrophy or fasciculations, either of which indicates damage to lower motor neurons, either peripherally or in the medulla. Tongue atrophy, if unilateral, causes reduction in size

on one side with excessive ridging and wrinkling of the affected side. Fasciculations in the tongue can be difficult to tell from normal tongue movements or tremor. These small local contractions are nonrhythmic and make the tongue resemble a *bag of worms*. They should be present when the tongue is completely at rest.

With unilateral weakness because of lesions of upper or lower motor neurons the tongue deviates toward the weak side. If there is no deviation, weakness is assessed by having the patient push the tongue into each cheek while the examiner pushes against the cheek. With unilateral lesions of upper motor neurons there may be no deviation and little evident weakness, yet patients may experience dysarthria (imperfect articulation), particularly with the lingual consonants (tay for anterior tongue, kay for the posterior tongue). Bilateral tongue weakness causes dysarthria, dysphagia, and sometimes even difficulty breathing.

Bilateral lesions of the lower brain stem can result in *bulbar palsy*. The tongue is paralyzed, atrophic, and fasciculating. There is no movement of the palate or pharynx with phonation, and the gag reflex is absent. With unilateral supranuclear lesions these muscles are often spared or only mildly impaired because of the bilateral cortical projections to lower brain stem motor neurons.

Bilateral lesions of the cerebrum or upper brain stem, however, can result in severe dysarthria and dysphagia because of effects on the corticobulbar pathway. The tongue is paralyzed but neither atrophic nor fasciculating. The palate and pharynx do not move with phonation, but the gag reflex is hyperactive. Such a patient is said to have *pseudobulbar palsy*. An interesting and unexplained feature of this syndrome is lability or hyperreflexia of emotional response. A remark that would normally produce a mild chuckle precipitates embarrassed peals of laughter, and asking a question such as "How are you feeling?" may result in explosive weeping.

Musculoskeletal System

Observations of spontaneous and commanded movements can reveal patterns of weakness that localize a lesion. Weakness of extensor muscle groups of the arm and flexors of the leg on the same side suggests a lesion of the corticospinal tract on the contralateral side. If the weakness is acute, the limbs may be flaccid; if chronic, there may be increased tone and brisk tendon reflexes (spasticity) (see Figure B–1).

Weakness of both legs (paraparesis) or of both legs and both arms (quadriparesis) may be the result of a lesion of the spinal cord or of widespread dysfunction of the peripheral nervous system or muscles. Lesions of the spinal cord may be associated with a sensory level (see section on Sensory Systems) or bladder dysfunction, and lesions above the spinal cord may be accompanied by signs of brain stem or cortical dysfunction. Peripheral neuropathies tend to produce a generally symmetrical pattern of limb weakness. As a rule, weakness that begins or is greater in the distal arms or legs suggests peripheral neuropathy, whereas weakness of the proximal limb muscles (shoulder and girdle) suggests myopathy (Figure B–3).

Weakness confined to a single limb may reflect plexopathy or mononeuropathy. Examining the strength of individual muscle groups innervated by specific nerves is key, and a chart of muscle innervation by nerve, trunk, and root can be a great aid in localization.

Observing Spontaneous Movement

The motor examination begins with observations of spontaneous movement, which may reveal patterns of weakness but may also reveal spontaneous uncontrolled movements such as tremor, athetosis, chorea, myoclonus, or dystonia. Fasciculations of individual muscle groups can sometimes be enhanced by directly tapping the muscle with a reflex hammer. If unilateral atrophy of limb musculature is suspected, the circumference of the limb should be measured and compared to the same region of the opposite limb.

Detecting a Lesion in the Corticospinal Tract

The patient's arms are held outstretched with palms upward and eyes closed. Mild corticospinal lesions may cause one arm to drift below the level of the other, with pronation of the upturned palm. A subtle sign of corticospinal pathology is clumsiness of fine finger movements, brought out by asking the patient to rapidly and steadily tap the forefinger against the thumb (finger-repetitive test), and then to tap each finger against the thumb in rapid succession (finger-successive test). One should compare the facility with which this is performed by each hand, bearing in mind that most people will be slightly more adept with their dominant side (see Figure B–1).

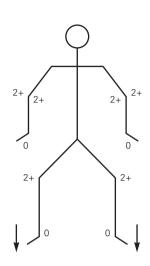

Testing Muscle Tone

With the patient relaxed, the arms are passively flexed and extended around the elbow and wrist joints. Muscle tone may be flaccid, which is usual following acute paralysis, lower motor neuron lesions, or myopathy; or it may be increased, often with a characteristic giveway relaxation after initial resistance (*clasp-knife* effect), reflecting spasticity and an upper motor neuron lesion.

A Glove and stocking hypoesthesia

Decreased pain and temperature Decreased vibration sense

B Distal hyporeflexia

C Abnormal nerve conduction study

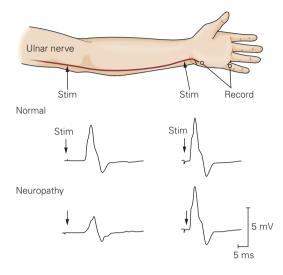

Figure B-3 Sensorimotor neuropathy associated with diabetes.

A. The patient initially complains of numbness in the distal legs, but with progression the hands also become involved. Diabetic neuropathy is an axonal neuropathy that affects both myelinated small fibers and unmyelinated C fibers. Because these sensory fibers subserve pain and temperature sensation, examination reveals decreased pain and temperature sensation. The findings are initially in the feet, but the signs and symptoms gradually ascend; by the time numbness extends to just below the knee, the hands are usually also involved in a "glove and stocking" distribution. Loss of sensation for vibration is also detectable.

B. Weakness of the limbs develops late and is greatest distally, especially in the intrinsic muscles of the feet and hands. The Achilles reflexes are diminished early, and finger flexor responses can be diminished by the time sensory changes are apparent in the hands.

C. Nerve conduction studies demonstrate changes characteristic of an axonal neuropathy. When the ulnar nerve is stimulated above the elbow or at the wrist, and the evoked hypothenar muscle response is measured in the hand, the evoked compound muscle action potential is reduced in amplitude but the latencies are normal.

Tone in the lower limbs may be tested in the supine patient by abruptly lifting the thigh. If the heel lifts briefly off the bed, tone is normal; if the leg rises rigidly off the bed, tone is increased; if the heel drags along the sheets, tone is decreased. Resistance to movement in all directions and throughout range of movement (lead-pipe rigidity) is characteristic of Parkinson disease; it may be accompanied by cogwheeling, a stepwise ratcheting that reflects the tremor of Parkinson disease superimposed on increased tone (Figure B–4).

Testing Muscle Strength

Muscle power is graded on a scale of 0 to 5 (0 = no contraction, 1 = contraction but no movement, 2 = contraction but not against gravity, 3 = movement against gravity but not against even minimal resistance, 4 = movement against minimal to moderate resistance, 5 = normal). Testing includes flexion and extension of the

head; abduction, adduction, and rotation of the shoulders; flexion and extension of the elbows, wrists, and fingers; intrinsic hand muscle movements; and flexion and extension of the hip, knee, ankle, and toes. Comparison is made between right versus left, proximal versus distal, and arms versus legs.

Sensory Systems

Establishing Boundaries and Comparing Sides Are Crucial to the Sensory Examination

As in the motor examination, patterns and symmetry are key. Distal symmetrical sensory loss is characteristic of peripheral neuropathies. Brain stem lesions, for example of the lateral medulla, produce pain and temperature loss ipsilaterally on the face and contralaterally on the body. Bilateral loss of all sensation below a

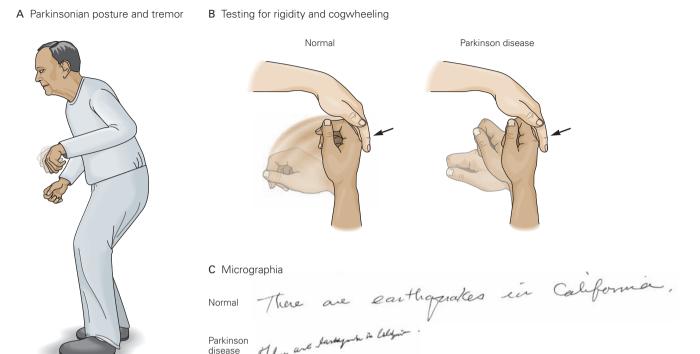

Figure B-4 Parkinson disease is manifested by akinesia, rigidity, and tremor.

A. Characteristic features of Parkinson disease include a stooped flexed posture, akinesia manifested as decreased arm swing when walking, and a resting tremor of four to five cycles per second (often involving the hands and typically with the forefinger rubbing against the thumb producing a *pill rolling* gesture).

B. Even at early stages, passively flexing and extending the patient's wrist while asking him to pretend to write using the

other hand will produce a stiffness of muscle tone that feels to the examiner like bending a lead rod (*lead pipe rigidity*). If a tremor is present, the examiner will feel a *cogwheel* or ratcheting motion rather than a smooth excursion.

C. An early manifestation is micrographia, manifested as a change in handwriting and demonstrated by asking the patient to write a sentence.

trunk level is characteristic of spinal cord lesions; the sensory level, the upper border of the area of sensory loss, is usually one or two segments higher on the back than on the chest. Preservation of sensation in the sacrum (sacral sparing) indicates an intraparenchymal lesion while loss of sensation indicates an extraparenchymal compressive lesion. Sacral sensory loss (saddle anesthesia) suggests a lesion of the cauda equina or conus medullaris.

Ipsilateral hyperalgesia, an increased sensitivity to pain, may be a result of nerve root irritation at the level of the lesion. Sensory loss develops throughout the root distribution as the lesion expands, and pain and temperature loss occurs in the contralateral leg when a spinal cord lesion produces spinothalamic tract dysfunction. There may also be ipsilateral loss of proprioception because of dorsal column dysfunction.

Spinal cord lesions arising within the cord, as in syringomyelia, can damage crossing spinothalamic fibers, causing segmental pain and temperature loss (for example, in a cape-like distribution throughout the shoulders and upper back if damage is in the upper cervical cord, or in the hands if damage is in the lower cervical cord) (Figure B–5).

Testing Pain Sensation

Pain is tested with a safety pin or the sharp end of a broken applicator stick, which should be disposed of after use. Pressing a pin against the bony part of a limb will be felt more sharply than a similar stimulus applied to a fleshy part. A single application of the pin should suffice; repetitive stimulation will increase the stimulus strength through temporal summation in receptor neurons.

Testing proceeds from head to toe in an orderly pattern, comparing locations on each side. Test spots should include proximal and distal upper and lower limbs, both front and back. Bearing in mind the sensory dermatomes (see Figure 22–9), a reasonable strategy is to test over the deltoid (C5), dorsal forearm (C6), thenar eminence (C6, but also median nerve), tip of the little finger (C8, ulnar nerve), medial forearm (T1), and axilla (T2). On the chest one should probe on either side of the midline and test along the back if a sensory level is detected on the chest or abdomen. Because C5 to T1 roots innervate the arms and hands, there is a C4/T2 boundary above the nipple line, and lower cervical cord lesions may produce a sensory level in this region. The lower limbs are tested over the thigh (L2), medial calf (L4), dorsum of the foot (L5), and lateral malleolus or sole of the foot (S1).

If areas of decreased sensation are detected, finer testing is necessary to map the borders and determine whether the lesion involves nerves, roots, or the central nervous system. In addition to anesthesia, patients may report either a dull sensation (hypalgesia), which may be as significant as anesthesia and just as useful in mapping patterns of deficit, or possibly hyperalgesia, which sometimes indicates the upper level of a spinal cord lesion.

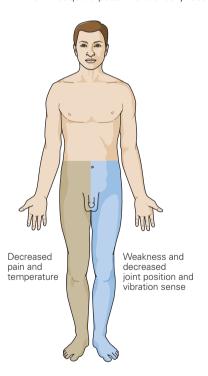

Temperature Testing

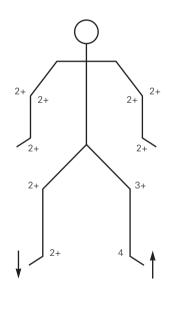

Pain and temperature are both carried centrally in the spinothalamic tract, so areas lacking hot or cold sensation will most often lack pain sensation as well. If pinprick testing has uncovered a deficit, testing temperature sensation by applying a cold tuning fork to the

A Brown-Sequard pattern of sensory loss

C Extradural compression at T8

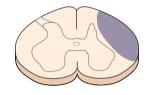

Figure B-5 Back pain with weakness and numbness in spinal cord compression.

A. Spinal cord compression by a tumor can produce a Brown-Séquard syndrome. The primary symptom is leg weakness, but there may be a radicular pattern of numbness on the side ipsilateral to the compression because of injury of the sensory root, and loss of pain and temperature sensation in the contralateral leg because of compression of the spinothalamic tract. Position and vibration sensation may be diminished in the ipsilateral leg because of compression of the dorsal columns.

B. The weak leg ipsilateral to the lesion has brisk tendon reflexes and a Babinski reflex as a result of involvement of the corticospinal tract.

C. The physical examination is suggestive of a lesion on the left side of the thoracic cord at the level of approximately T8. A magnetic resonance imaging scan confirms extradural cord compression by a tumor mass at T8.

skin for several seconds can be a very useful procedure to confirm involvement of spinothalamic modalities.

Touch Testing

Testing light touch sensation is not helpful in localizing central lesions because touch sensation is carried by several spinal tracts, but it is very helpful in localizing peripheral lesions of nerves or roots. Testing should follow the procedure for testing pain by stroking lightly with a finger or a cotton wisp. Deficits may include a simple decrease in sensation (hypesthesia), a distorted or abnormal sensation (dysesthesia), or even a painful sensation (allodynia).

Testing Proprioception

With eyes closed one can still sense the position of one's arms and legs because of proprioceptive nerve endings in the joints that convey sensory information by way of the dorsal columns of the spinal cord. To test position sense in the elbow and shoulder, ask the patient to extend the arms with eyes closed and to touch the forefinger to the tip of the nose.

Position sense in the fingers (or wrist) is tested by asking the patient with eyes closed to identify whether the finger (or wrist) has been moved up or down by the examiner. Grasp the patient's finger at the sides rather than the dorsal and palmar surfaces to ensure that the patient does not use pressure sense to judge direction of movement. Position sense is very sensitive; only 1 to 2 millimeters of displacement is required. In rare instances of loss of proprioception the arms may drift into odd dystonic postures (pseudoathetosis) when the eyes are closed.

To test the hip and knee joints, ask the supine patient with eyes closed to identify when the leg has been moved to a new position, or to point to the big toe as the leg is moved to a series of positions. Proprioception of the big toe is tested as for the fingers.

The Romberg test for balance is performed by asking the patient to stand unassisted with feet together and eyes closed. The test is considered positive if the patient loses balance. Although dorsal column lesions produce a positive test, so will a variety of other conditions, including inner ear dysfunction and cerebellar lesions. Sensory ataxia, a gait disorder resulting from uncertainty concerning limb position, indicates posterior column lesions.

Testing Vibration Sensation

Vibration is tested with a 128 Hz tuning fork held against the bony wrist and the lateral malleolus of the ankle. Place the stem firmly against the patient's

wrist or ankle and instruct the patient to signal when the vibration has stopped. To ensure that sensation has not ceased because of habituation, promptly remove and replace the fork to test whether the patient can still feel vibration; when the patient declares the vibration has stopped, place the fork against your own wrist to confirm that it is no longer vibrating. Vibration sensation can also be tested at the toes, knees, and elbows. Decreased vibratory sensation at the toes and ankles is a sensitive measure of sensory peripheral neuropathy (see Figure B–3).

Complete spinal cord transection will produce bilateral hyperesthesia at the level of the lesion and loss of sensation in all modalities beginning several segments below. Hemisection of the spinal cord (Brown-Séquard syndrome) produces ipsilateral loss of vibration and position sense and contralateral loss of pain and temperature a few levels below the lesion (see Figure B–5). Central cord lesions, such as syringomyelia, injure the spinothalamic fibers as they cross just anterior to the spinal canal, producing bilateral loss of pain and temperature at the level of the lesion while sparing other modalities such as light touch and proprioception.

Testing Cortical Processing of Touch

Sensory information originating in the pathways tested above is processed in the cerebral cortex. But findings from tests of perception will only be significant once the elementary sensory pathways for touch have been found to be intact.

The patient, with arms outstretched and eyes closed, is asked to state which hand has been touched. The examiner lightly touches first one hand, then the other, and then both simultaneously. Patients suffering from spatial neglect may correctly identify single touches on both sides but consistently fail to report a touch on one side when both sides are touched simultaneously (double simultaneous stimulation). This deficit, termed sensory extinction, implicates a lesion of the contralateral parietal lobe.

Graphesthesia is tested by having the patient with eyes closed identify numbers from 1 to 10 traced on the palm of each hand using a pointed but blunt instrument. The traced numbers should be right side up with respect to the patient.

The patient's ability to identify objects by touch (stereognosis) is tested by asking the patient with eyes closed to identify a common object such as a key, comb, or coin that is placed in the palm. The patient is permitted to manipulate the object with his fingers. As always, performance on the right is compared to the left.

Two-point discrimination is tested by first applying a single stimulus, then two stimuli simultaneously and asking the patient with eyes averted to identify these correctly. The separation that can be discriminated will vary with the density of sensory innervation over different skin regions; thus the fingertips can detect the smallest separations. The same areas on both sides should be compared.

Motor Coordination

Testing coordination and involuntary movement assesses cerebellar and basal ganglia function. Involuntary movements include tremors (repetitive, oscillatory motions), myoclonus (sudden twitching of muscle groups), asterixis (periodic lapse of muscle tone), chorea (rapid, chaotic twitching), athetosis ("wormian" writhing motions), dystonia (athetotic-like movements with held postures), and ballism (proximal flinging movements of the arms).

These movements are best observed with the patient at rest with arms outstretched. Asterixis is brought out by having the patient hold hands dorsiflexed at the wrist in the position used by traffic policeman to command "stop." Periodic lapse of posture (the "wave good-bye" sign) is positive for asterixis. Tremors are classified as resting, postural, and action. Postural tremors can be assessed by having the patient hold the arms in the outstretched posture, whereas action tremors can be assessed by having the patient touch first the examiner's finger and then his own nose. Resting tremors are best assessed by observing the patient seated, lying down, or walking with arms hanging down.

The term *ataxia* (literally, disorder) refers to a variety of impairments of coordination as well as unsteady gait most often following a cerebellar lesion. Cerebellar lesions cause ipsilateral rebound, dysmetria, and dysdiadochokinesia. *Rebound* is tested by applying downward pressure against the patient's outstretched arms and releasing abruptly. If rebound is present, the arms will fly up rather than return to the neutral position. *Dysmetria* consists of overshooting or undershooting the target. In the arms dysmetria is detected with the same finger-to-finger and finger-to-nose test used to detect action tremor, which often coexists. In the legs dysmetria (and action tremor) can be detected by having the patient place a heel on the opposite knee and run it down the shin.

Dysdiadochokinesia, the inability to maintain a steady rhythmic movement, is identified by having the patient perform rapid successive movements (for example, tapping the thumb and index finger together, or one hand against the other, or tapping a foot on the floor) and rapid alternating movements (for example, alternately pronating and supinating the hands or alternately tapping the toe and heel of one foot on the floor).

Gait and Stance

The patient is asked to stand and walk normally 5 to 10 paces, then turn around and walk back. Observations should be made of posture, arm swing, foot position, step size, and dexterity of motion, especially during turning. During walking the insteps of both feet normally line up along an imaginary line; when there is an increase in the distance between the two feet, the gait is broad-based and suggestive of cerebellar disease or proprioceptive loss.

With flaccid hemiparesis the affected arm has diminished swing and the affected leg may drag (footdrop). When footdrop occurs in isolation, as for example with peroneal nerve injury, the patient may have a "steppage" gait, lifting the leg higher than normal to compensate for foot dragging. With spastic hemiparesis the affected side shows hemiparetic posture, with the arm flexed at the elbow and wrist and leg extended and inverted (see Figure B-1). Gait therefore has a circular form (circumduction) as the patient swings the affected leg off the ground by throwing his body to the opposite side. The foot describes a circular motion with each step. With spastic paraparesis or quadriparesis, as occurs with cerebral palsy, bilateral extensor tone may produce toe-walking or scissoring as a result of bilateral circumduction. Parkinsonian gait is characterized by a forward stoop, loss of arm swing, shuffling, and festination (acceleration, as if the patient were trying to catch up with his center of gravity) (see Figure B–4).

Myopathic gait is characterized by waddling, the result of bilateral hip abductor weakness. Antalgic gait refers to gait in which compensatory maneuvers (eg, favoring one leg) are adopted to minimize pain. Subtle signs of hemiparesis can be detected with the use of stressed gaits, such as walking on toes, heels, or the outside edges of the feet. Note the position of the arms during these gaits for evidence of synkinesia.

Synkinesia or *overflow movement* is said to occur when the ipsilateral arm and hand posture mimics the position of the foot. Such associated movements are normal in very young children and tend to be prominent in cases of cerebral palsy, but are not normal in adults. Unilateral hand-foot overflow movements can be seen in mild cases of hemiparesis.

Balance

Patients are asked to walk a straight line as though on a tight rope, one foot in front of the other. Any deviation from a straight path is noted. This test is sensitive for cerebellar ataxia of gait, as occurs with alcohol intoxication, and is thus the basis of the field sobriety test. However, patients with lesions of the cerebellum for any cause will demonstrate a *drunken gait*, as can patients with labyrinthine dysfunction, dizziness, weakness, balance trouble, or proprioceptive problems.

Patients with severe cerebellar ataxia or vertigo may not be able to stand with feet together. After examining and establishing the stability of the patient's stance, the patient is told to close his eyes. The Romberg test may identify more subtly impaired stance.

Deep Tendon Reflexes

Examining tendon reflexes can confirm whether weakness is due to damage of lower or upper motor neurons. Increased reflexes indicate damage in upper motor neurons; diminished reflexes indicate damage to lower motor neurons (see Figure B–1). Rating is on a scale of 0 to 5, where 0 = absent, 1 = reduced, 2 = normal, 3 = brisk without clonus, 4 = transient clonus, and 5 = sustained clonus. Reflexes of 4 or 5 are usually pathological, but hypoactive reflexes are often normal.

Both sides are compared and reproducible asymmetry is always significant. Tendon reflexes are elicited by tapping a stretched tendon to activate the muscle spindle. The muscle to be tested should be relaxed and not under active contraction. If a tendon response appears to be absent, the response may be enhanced by having the patient perform some task, for example interlocking the fingers of both hands and attempting to pull them apart as the examiner elicits the reflex.

Tendon Reflexes in the Arms

To elicit a biceps reflex the arm is flexed 90 degrees at the elbow; pressure is applied to the biceps tendon using an extended forefinger and then a phasic stretch is elicited by striking the forefinger with the reflex hammer. To elicit the triceps reflex the elbow is also held at 90 degrees and the tendon is struck directly with the hammer. The brachioradial muscle is tested by holding the patient's hand with the elbow flexed and striking the radius just above the wrist.

Finger flexors are tested by having the patient gently flex the fingers against the examiner's outstretched

forefinger and then striking the forefinger with the hammer to apply a sudden extension. Brisk reflexes may be associated with reflex spread. For example, stretching the finger flexors may cause the thumb to flex as well, and flicking the nail of the patient's forefinger may similarly trigger finger and thumb flexion (Hoffmann reflex).

Tendon Reflexes in the Legs

The patellar reflex is best elicited with the patient either sitting with legs crossed or supine. The leg is lifted from behind the knee and the patellar tendon is struck below the knee. If the patella reflex is very brisk, clonus may be elicited by extending the leg and, while holding the patella between thumb and forefinger, applying a sharp downward stretch. Reflex spread may include a crossed adductor response, elicited in the supine patient by pressing on the medial knee to slightly spread (abduct) the leg and then striking the hand with the hammer. Adduction of both legs suggests pathological briskness.

The ankle reflex is best elicited with the leg tripleflexed (at the hip, knee, and ankle). The ankle is then dorsiflexed by applying pressure to the ball of the foot with the hand. Striking either this hand or the Achilles tendon with the reflex hammer will produce a sudden stretch of the gastrocnemius tendon and trigger the reflex. In this position it is easy to observe clonus, if present. Ankle clonus usually accompanies spasticity.

Asymmetrical Superficial Reflexes

The plantar response is conveniently tested following the ankle reflex. A blunt instrument (a key or wooden applicator stick) is used to stroke up along the lateral edge of the sole and across the plantar surface. The big toe should be observed for extension and the remaining toes for possible fanning, an *extensor plantar response* (Babinski reflex). A flexor motion or no toe motion at all can be normal, but a neutral response on one side may be significant in the presence of a clear flexor response on the other side. Babinski reflex indicates a corticospinal lesion (see Figure B–1).

Abdominal reflexes are elicited by drawing a blunt instrument across the abdomen several inches to one side of the umbilicus and then repeating the maneuver on the other side. A normal response is movement of the umbilicus toward the side of stimulation. Symmetrically absent responses are not significant, but an asymmetrically absent response can be associated with upper motor neuron lesions.

Frontal Lobe Reflexes

Several so-called frontal release signs or primitive reflexes have been described. These include the snout reflex, elicited by tapping the mouth gently with the reflex hammer and observing whether the lips purse; the palmomental reflex, elicited by scratching the palm and observing contraction of the mentalis muscle; and the grasp reflex, triggered by stroking the palm and

triggering an involuntary grasp. These responses are often associated with frontal lobe lesions, but, with the exception of the grasp reflex, they are also present in many normal adults.

The Rupture of Microaneurysms Causes Intraparenchymal Stroke

The Rupture of Saccular Aneurysms Causes Subarachnoid Hemorrhage

Stroke Alters the Vascular Physiology of the Brain

THE BRAIN IS HIGHLY VULNERABLE to disturbance of its blood supply. Anoxia lasting only seconds causes neurological symptoms; when it lasts

minutes it can cause irreversible neuronal damage. Blood flow to the central nervous system must efficiently deliver oxygen, glucose, and other nutrients and remove carbon dioxide, lactic acid, and other metabolites. The cerebral vasculature has special anatomical and physiological features that protect the brain. However, when these mechanisms fail, the result is a stroke. Broadly defined, the term *stroke*, or *cerebrovascular accident*, refers to the neurological symptoms or signs that result from diseases involving blood vessels. These are usually focal and acute.

The Blood Supply of the Brain Can Be Divided into Arterial Territories

Each cerebral hemisphere is supplied by an *internal* carotid artery, which arises from the common carotid artery beneath the angle of the jaw, enters the cranium through the carotid foramen, traverses the cavernous sinus (giving off the *ophthalmic artery*), penetrates the dura, and then divides into the anterior and middle cerebral arteries (Figure C–1).

The large surface branches of the *anterior cerebral artery* supply the cortex and white matter of the inferior frontal lobe, the medial surface of the frontal and parietal lobes, and the anterior corpus callosum (Figure C–2). Smaller penetrating branches—including the so-called *recurrent artery of Heubner*—supply the deeper cerebrum and diencephalon, including limbic structures, the head of the caudate, and the anterior limb of the internal capsule.

The large surface branches of the *middle cerebral* artery supply most of the cortex and white matter of the hemisphere's convexity, including the frontal, parietal, temporal, and occipital lobes, and the insula

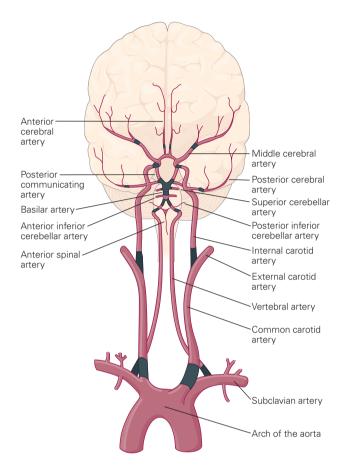

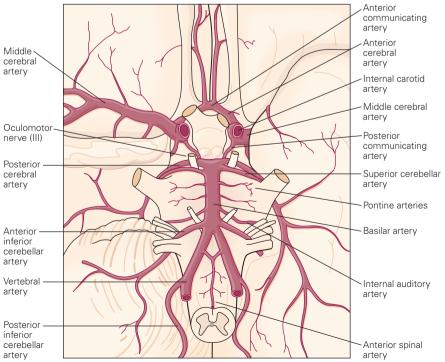

Figure C-1 The blood vessels of the brain. The circle of Willis is made up of the proximal posterior cerebral arteries, posterior communicating arteries, internal carotid arteries just before their bifurcations, proximal anterior cerebral arteries, and anterior communicating artery. Black areas are common sites of atherosclerosis and occlusion.

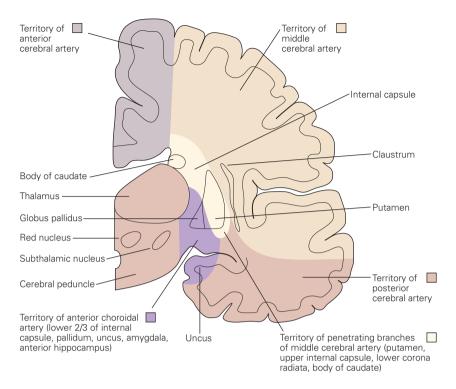

Figure C-2 Cerebral arterial areas.

(Figure C–2). Smaller penetrating branches (the *lenticulostriate arteries*) supply the deep white matter and diencephalic structures, such as the posterior limb of the internal capsule, putamen, outer globus pallidus, and body of the caudate. After the internal carotid emerges from the cavernous sinus, it also gives off the *anterior choroidal artery*, which supplies the anterior hippocampus and, at a caudal level, the posterior limb of the internal capsule.

Left and right vertebral arteries arise from the subclavian arteries and enter the cranium through the foramen magnum. Each gives off an anterior spinal artery and a posterior inferior cerebellar artery. The vertebral arteries join at the junction of the pons and medulla to form the basilar artery, which at the pontine level gives off the anterior inferior cerebellar artery and the *internal auditory artery* and at the midbrain level the superior cerebellar artery. The basilar artery then divides into the two posterior cerebral arteries, which supply the inferior temporal and medial occipital lobes and the posterior corpus callosum (Figure C-2). The smaller penetrating branches of these vessels (the thalamoperforate and thalamogeniculate arteries) supply diencephalic structures, including the thalamus and the subthalamic nuclei, as well as parts of the midbrain.

Interconnections between blood vessels (anastomoses) protect the brain when part of its vascular supply is blocked (Figure C-3). At the circle of Willis, which provides an overlapping blood supply, the two anterior cerebral arteries are connected by the anterior communicating artery, and the posterior cerebral arteries are connected to the internal carotid arteries by the posterior communicating arteries. Other important anastomoses include connections between the ophthalmic artery and branches of the external carotid artery through the orbit, and connections at the brain surface between branches of the middle, anterior, and posterior cerebral arteries (sharing border zones or watersheds). The small penetrating vessels arising from the circle of Willis and proximal major arteries tend to lack anastomoses. The deep brain regions they supply are therefore referred to as end zones (no source of overlapping blood supply).

The Cerebral Vessels Have Unique Physiological Responses

Although the human brain constitutes only 2% of total body weight, it receives approximately 15% of the

cardiac output and consumes approximately 20% of the oxygen used by the entire body. These values reflect the high metabolic rate and oxygen requirements of the brain. The total blood flow to the brain is 750 to 1000 mL/min; approximately 350 mL of this amount flows through each carotid artery and approximately 100 to 200 mL flow through the vertebrobasilar arterial system. Flow per unit mass of gray matter (somata and dendrites) is approximately four times that of white matter (axons).

Cerebral vessels are capable of altering their own diameter and can respond to altered physiological conditions. Two main types of autoregulation exist. Brain arterioles constrict when the systemic blood pressure is raised and dilate when it is lowered. These adjustments help maintain optimal cerebral blood flow. The result is that normal people have a constant cerebral blood flow between mean arterial pressures of 60 to 150 mm Hg. Above or below these pressures cerebral blood flow rises or falls linearly.

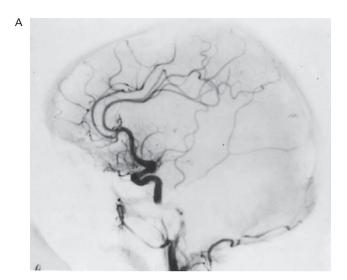

The second type of autoregulation involves blood or tissue gases and pH. When arterial carbon dioxide (CO₂) is raised, brain arterioles dilate and cerebral blood flow increases; with hypocarbia, vasoconstriction results and cerebral blood flow decreases. The response is sensitive: Inhalation of 5% CO₂ increases blood flow by 50%; 7% CO₂ doubles it. Changing arterial O₂ causes an opposite and less pronounced response. Breathing pure O₂ lowers blood flow by approximately 13%; 10% O₂ raises it by 35%. The mechanism of these responses is uncertain. The vasodilatory action of arterial CO₂ is probably mediated by alterations in extracellular pH. Local concentrations of K⁺ and adenosine, both of which cause vasodilation, may play a role.

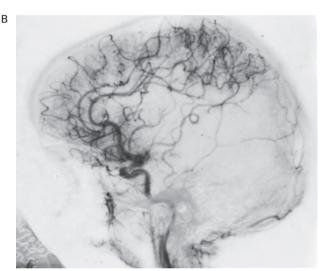

Whatever the mechanism, these responses protect the brain by increasing the delivery of oxygen and the removal of acidic metabolites under conditions of hypoxia, ischemia, or tissue damage. They also allow nearly instantaneous adjustments of regional cerebral

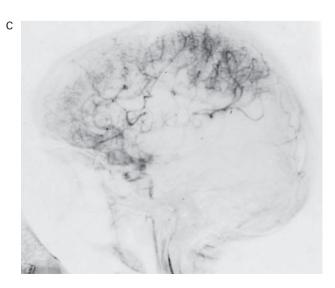

Figure C-3 Angiograms demonstrate the importance of anastomoses in allowing retrograde filling after occlusion of the middle cerebral artery. (Reproduced, with permission, from Margaret Whelan and Sadek K. Hilal.)

A. Occlusion of the middle cerebral artery results in no filling in the middle cerebral distribution.

- **B.** Retrograde filling of the middle cerebral artery has begun via distal anastomotic branches of the anterior cerebral artery.
- C. Retrograde filling of the middle cerebral artery continues at a time when little contrast material is seen in the anterior cerebral artery.

blood flow to meet the demands of rapidly changing oxygen and glucose metabolism that accompany normal brain activities. For example, viewing a complex scene increases oxygen and glucose consumption in the visual cortex of the occipital lobes. The resulting increased CO₂ concentration and lowered pH in the area rapidly increase local blood flow.

A Stroke Is the Result of Disease Involving Blood Vessels

Diseases of blood vessels are among the most frequent serious neurological disorders, ranking third as a cause of death in the adult population in the United States and probably first as a cause of chronic functional incapacity. Approximately two million Americans today are impaired by the neurological consequences of cerebrovascular disease, many between 25 and 64 years of age.

Strokes are either occlusive (closure of a blood vessel) or hemorrhagic (bleeding from a vessel). Insufficiency of blood supply is termed *ischemia*; if it is temporary, symptoms and signs may clear with little or no pathological evidence of tissue damage. Ischemia results in more than simply *anoxia*, because a reduced blood supply deprives tissue not only of oxygen but also of glucose. In addition, it prevents the removal of potentially toxic metabolites such as lactic acid. When ischemia is sufficiently severe and prolonged, neurons die; this condition is called *infarction*.

Hemorrhage may occur at the surface of the brain (extraparenchymal), for example from rupture of saccular aneurysms at the circle of Willis, causing subarachnoid hemorrhage. Alternatively, hemorrhage may be intraparenchymal, for example from rupture of vessels damaged by chronic hypertension—and may cause a blood clot or *hematoma* within the cerebral hemispheres, brain stem, or cerebellum. Hemorrhage may result in ischemia or infarction. Because of its mass, an intracerebral hematoma may limit the blood supply of adjacent brain tissue. By mechanisms that are not understood, subarachnoid hemorrhage may cause reactive vasospasm of cerebral surface vessels, leading to further ischemic brain damage.

Although most occlusive strokes are caused by atherosclerosis and thrombosis and most hemorrhagic strokes are associated with hypertension or aneurysms, strokes of either type may occur at any age from many other causes, including cardiac disease, trauma, infection, neoplasm, blood dyscrasia, vascular malformation, immunological disorder, and exogenous toxins.

Clinical Vascular Syndromes May Follow Vessel Occlusion, Hypoperfusion, or Hemorrhage

Infarction Can Occur in the Middle Cerebral Artery Territory

Infarction in the territory of the middle cerebral artery (Figure C–4) causes the most frequently encountered stroke syndrome, with contralateral weakness, sensory loss, and visual field impairment (homonymous hemianopia), and, depending on the hemisphere involved, either language disturbance (left) or impaired spatial perception (right). Weakness and sensory loss affect the face and arm more than the leg because of the somatotopy of the motor and sensory cortex (pre- and postcentral gyri). The face- and arm-control areas are on the convexity of the hemisphere, whereas the leg-control area is on the medial surface.

Motor and sensory loss are greatest in the hand because the more proximal limbs and the trunk tend to have greater representation in both hemispheres. Paraspinal muscles, for example, are rarely weakened in

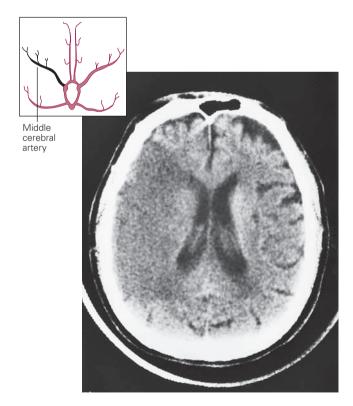

Figure C-4 Computed tomography scan showing infarction (dark area) in the territory of the middle cerebral artery. (Reproduced, with permission, from Allan J. Schwartz.)

unilateral cerebral lesions. Similarly, the facial muscles of the forehead and the muscles of the pharynx and jaw are represented in both hemispheres and therefore are usually spared. Tongue weakness is variable. If weakness is severe (plegia), muscle tone is usually decreased at first but gradually increases over days or weeks to spasticity with hyperactive tendon reflexes. A Babinski sign, reflecting upper motor neuron disturbance, is usually present. When weakness is mild, or during recovery, there may be clumsiness or slowness of movement out of proportion to loss of strength; such motor disability may resemble parkinsonian bradykinesia or even cerebellar ataxia.

Acute paresis of contralateral conjugate gaze often occurs as a result of damage to the convexity of the frontal cortex anterior to the motor cortex (the frontal eye field). For reasons that are unclear, this gaze palsy persists for only one or two days, even when other signs remain severe.

Sensory loss tends to involve discriminative and proprioceptive modalities more than affective modalities (pain and temperature sensation), which may be impaired or altered but are usually not lost completely. Joint position sense may be severely disturbed, causing limb ataxia, and there may be loss of two-point discrimination, astereognosis (inability to recognize an object by tactile sensation alone), or extinction (failure to appreciate a touch stimulus if a comparable stimulus is delivered simultaneously to the unaffected side of the body).

Homonymous hemianopia is the result of damage to the optic radiations, the deep fiber tracts connecting the thalamic lateral geniculate nucleus to the visual (calcarine) cortex. If the parietal radiation is primarily affected, the visual field loss may be an inferior quadrantanopia, whereas in temporal lobe lesions quadrantanopia may be superior.

In more than 95% of right-handed persons and most of those who are left handed, the left hemisphere is dominant for language. Destruction of left frontal, parietal, or temporal opercular (perisylvian) cortex in leftdominant people causes aphasia, which takes several forms depending on the degree and distribution of the damage. Frontal opercular lesions tend to produce particular difficulty with speech output and writing while preserving at least partially language comprehension (Broca aphasia). Infarction of the posterior superior temporal gyrus tends to cause severe difficulty in speech comprehension and reading (Wernicke aphasia). When damage to the opercular cortex is widespread, a severe disturbance of mixed type occurs (global aphasia). Lefthemisphere convexity damage, especially parietal, also causes motor apraxia, a disturbance of learned motor acts not explained by weakness or incoordination.

Right-hemisphere convexity infarction, especially parietal, causes disturbances of spatial perception. Patients may have difficulty in copying simple diagrams (constructional apraxia), interpreting maps or finding their way about (topographagnosia), or putting on their clothing properly (dressing apraxia). Awareness of space and the patient's own body on the side contralateral to the lesion may be particularly impaired (hemi-inattention or hemineglect). Patients also fail to acknowledge their hemiplegia (anosognosia), left arm (asomatognosia), or any external object to the left of their own midline.

Particular types of language or spatial dysfunction tend to result from occlusion of one of the several main pial branches of the middle cerebral artery, not the proximal stem. In these circumstances other signs (eg, weakness or visual field defect) may be absent. Similarly, occlusion of the rolandic branch of the middle cerebral artery causes motor and sensory loss affecting the face and arm without disturbing vision, language, or spatial perception.

Infarction Can Occur in the Anterior Cerebral Artery Territory

Infarction in the territory of the anterior cerebral artery (Figure C–5) causes weakness and sensory loss qualitatively similar to that of convexity lesions, but infarction in this territory affects mainly the distal contralateral leg. Urinary incontinence may be present, but it is uncertain whether this is because of a lesion of the paracentral lobule (medial hemispheric motor and sensory cortices) or a more anterior region necessary for the inhibition of bladder emptying. Damage to the supplementary motor cortex disturbs speech. Involvement of the anterior corpus callosum causes apraxia of the left arm (*sympathetic apraxia*), which is attributed to disconnection of the left (language-dominant) hemisphere from the right motor cortex.

Bilateral infarction in the territory of the anterior cerebral artery (occurring, for example, when both arteries arise anomalously from a single trunk) causes abulia, a severe behavioral disturbance consisting of profound apathy, motor inertia, and muteness, and attributable to destruction of the inferior frontal lobes (orbitofrontal cortex), deeper limbic structures, supplementary motor cortices, and cingulate gyri.

Infarction Can Occur in the Posterior Cerebral Artery Territory

Infarction in the territory of the posterior cerebral artery (Figure C–6) causes contralateral homonymous

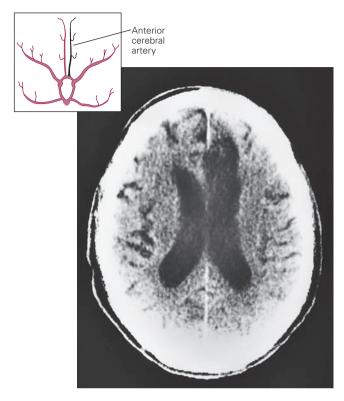

Figure C-5 Computed tomography scan showing infarction (dark area) in the territory of the anterior cerebral artery. (Reproduced, with permission, from Allan J. Schwartz.)

hemianopsia by destroying the medial occipital cortex. Macular (central) vision tends to be spared because the occipital pole, where macular vision is represented, receives anastomotic blood supply from the middle cerebral artery. If the lesion is on the left and the posterior corpus callosum is affected, alexia—the inability to read—may be present without aphasia or agraphia. A possible explanation for the alexia is the disconnection of the right occipital cortex (visual processing) from the language-dominant left hemisphere. If infarction is bilateral (eg, following thrombosis at the point where both posterior cerebral arteries arise from the basilar artery), there may be cortical blindness that is not recognized by the patient (Anton syndrome), or memory disturbance as a result of bilateral damage to the inferomedial temporal lobes.

If the posterior cerebral artery occlusion is proximal, the following structures may be damaged: the thalamus, causing contralateral hemisensory loss and sometimes dysesthesia (altered touch sensation) and spontaneous pain (thalamic pain syndrome); the subthalamic nucleus, causing contralateral severe proximal

chorea (hemiballism); or even the midbrain, with ipsilateral oculomotor palsy and contralateral hemiparesis or ataxia from involvement of the corticospinal tract or the crossed superior cerebellar peduncle (dentatothalamic tract).

The Anterior Choroidal and Penetrating Arteries Can Become Occluded

Anterior choroidal artery occlusion can cause contralateral hemiplegia and sensory loss from involvement of the posterior limb of the internal capsule and homonymous hemianopia from involvement of the thalamic lateral geniculate nucleus.

The deeper cerebral white matter and diencephalon are supplied by small penetrating arteries, which arise from the circle of Willis or the proximal portions of the middle, anterior, and posterior cerebral arteries. Occlusion of these end-arteries causes small infarcts (less than 1.5 cm in diameter) called *lacunes* with characteristic syndromes. For example, lacunes in the pyramidal tract area of the internal capsule cause

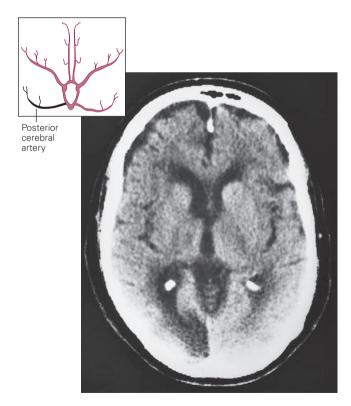

Figure C–6 Computed tomography scan showing infarction (dark area) in the territory of the posterior cerebral artery. (Reproduced, with permission, from Allan J. Schwartz.)

pure hemiparesis, with face, arm, and leg weakness of equal severity but little or no sensory loss, visual field disturbance, aphasia, or spatial disruption. Lacunes in the ventral posterior nucleus of the thalamus produce pure hemisensory loss, with involvement of pain, temperature, proprioceptive, and discriminative modalities and with little motor, visual, language, or spatial disturbance. Most lacunes occur in redundant areas (eg, nonpyramidal corona radiata) and so are not symptomatic. If bilateral and numerous, however, they may cause a characteristic syndrome (état lacunaire) of progressive dementia, shuffling gait, and pseudobulbar palsy (spastic dysarthria and dysphagia, with lingual and pharyngeal paralysis and hyperactive palate and gag reflexes, plus lability of emotional response, with abrupt crying or laughing out of proportion to mood).

Infarction restricted to structures supplied by the recurrent artery of Heubner or other deep penetrating branches of the anterior cerebral artery (the anterior caudate nucleus and, less predictably, the anterior putamen and anterior limb of the internal capsule) results in varying combinations of psychomotor slowing, dysarthria, agitation, contralateral neglect, and, when left hemispheric, language disturbance.

The Carotid Artery Can Become Occluded

Atherothrombotic vessel occlusion often occurs in the internal carotid artery rather than the intracranial vessels. Particularly in a patient with an incomplete circle of Willis, infarction may include the territories of both the middle and anterior cerebral arteries, with arm and leg weakness and sensory loss equally severe. Alternatively, infarction may be limited to the distal shared territory (border zones) of these vessels, destroying motor cortex at the upper cerebral convexity and producing weakness limited to the arm or the leg.

The Brain Stem and Cerebellum Are Supplied by Branches of the Vertebral and Basilar Arteries

Branches of the vertebral and basilar arteries consist of three groups: (1) paramedian branches, including the anterior spinal artery, supply midline structures; (2) short circumferential branches supply more lateral structures, including the inferior, middle, and superior cerebellar peduncles; and (3) long circumferential arteries—the posterior inferior, anterior inferior, and superior cerebellar arteries—also supply lateral brain stem structures and the cerebellar peduncles, as well as the cerebellum itself. Most of the midbrain is supplied by branches of the posterior cerebral artery. The

interpeduncular branches, the most medial branches located between the basilar artery bifurcation and the posterior communicating arteries, supply paramedian midbrain structures. Lateral to this group are the thalamoperforate branches, which supply the inferior, medial, and anterior thalamus and the subthalamic nucleus. Further laterally are the thalamogeniculate branches, which supply lateral and dorsal structures in the midbrain and thalamus. In some people the midbrain also receives blood from the superior cerebellar, posterior communicating, and anterior choroidal arteries. After passing around the midbrain, the posterior cerebral artery enters the middle fossa to supply the occipital and inferior temporal lobes. It does not supply the cerebellum.

Damage to specific brain stem structures produces a variety of syndromes (Figure C–7). With the exception of the lateral medullary syndrome of Wallenberg, however, most original descriptions of these syndromes were based on patients with neoplasms. Brain stem infarction more often follows occlusion of the vertebral or basilar arteries themselves rather than their medial or lateral branches; resulting syndromes and signs tend to be less stereotyped than originally described.

Generally speaking, a lesion of the posterior fossa is suggested by (1) bilateral long tract (motor or sensory) signs, (2) crossed (eg, left face and right limb) motor or sensory signs, (3) cerebellar signs, (4) stupor or coma (from involvement of the ascending reticular activating system), (5) disconjugate eye movements or nystagmus, and (6) involvement of cranial nerves not usually affected by unilateral hemispheric infarcts (eg, unilateral deafness or pharyngeal weakness). Sometimes a lesion involving only a single tiny structure can be localized accurately by symptomatology. For example, internuclear ophthalmoplegia implicates a lesion of the median longitudinal fasciculus. Other lesions produce more ambiguous symptoms. For example, infarction limited to the upper pontine corticospinal tract can produce contralateral face, arm, and leg weakness indistinguishable from that caused by a small infarct in the internal capsule.

Infarcts Affecting Predominantly Medial or Lateral Brain Stem Structures Produce Characteristic Syndromes

Medullary and pontine syndromes are conveniently viewed as lateral or medial (Figure C–7). Infarction of the lateral medulla follows occlusion of the vertebral artery or less often the posterior inferior cerebellar artery. Symptoms and signs include (1) vertigo, nausea, vomiting, and nystagmus (from involvement of

(paramedian branches of basilar artery)

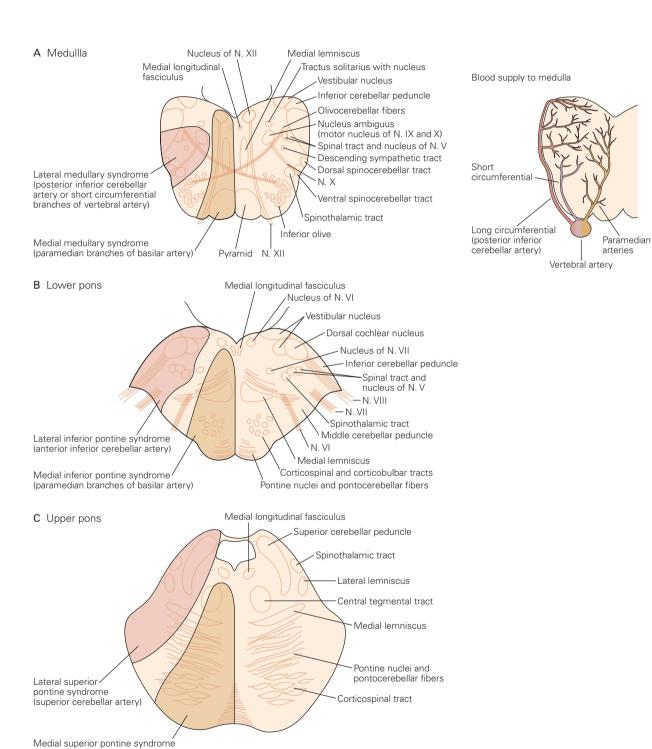

Figure C-7 Syndromes of brain stem vascular lesions (indicated on the left in each figure).

the vestibular nuclei); (2) ataxia of gait and ipsilateral limbs (inferior cerebellar peduncle or the cerebellum itself); (3) decreased pain and temperature (but not touch) sensation on the ipsilateral face (spinal tract and nucleus of the trigeminal nerve) and the contralateral body (spinothalamic tract); (4) dysphagia, hoarseness, ipsilateral weakness of the palate and vocal cords, and ipsilaterally decreased gag reflex (nucleus ambiguus, or glossopharyngeal and vagus outflow tracts); and (5) ipsilateral Horner syndrome (descending sympathetic fibers). Involvement of the nucleus solitarius can cause ipsilateral loss of taste, and hiccups are often present. The symptoms and signs for infarcts affecting different levels of the brain stem are listed in Table C–1.

Infarction of the medial medulla causes contralateral hemiparesis (from involvement of the corticospinal tract), ipsilateral tongue weakness with dysarthria and deviation toward the paretic side (hypoglossal nucleus or outflow tract), and contralateral impaired proprioception and discriminative sensation with preserved pain and temperature sensation (medial lemniscus).

Infarction of the lateral pons affects caudal structures when the anterior inferior cerebellar artery is occluded and rostral structures when the superior cerebellar artery is occluded (Figure C-8). Symptoms of caudal damage resemble those of lateral medullary infarction, with vertigo, nystagmus, gait and ipsilateral limb ataxia, crossed face-and-body pain and temperature loss, Horner syndrome, and ipsilateral loss of taste. There is also unilateral tinnitus and deafness (from involvement of the cochlear nuclei). Involvement of more medial structures can cause ipsilateral gaze paresis or facial weakness. Symptoms of rostral damage include gait and ipsilateral limb ataxia, Horner syndrome, and crossed sensory loss, which at this level includes touch as well as pain and temperature sensation on the ipsilateral face (from involvement of the primary sensory nucleus or entering sensory fibers of the trigeminal nerve). There may also be ipsilateral jaw weakness with deviation to the paretic side (trigeminal motor nucleus and outflow tract). Vertigo, deafness, and face weakness are not present.

Infarction of the medial pons, whether caudal or rostral, causes contralateral hemiparesis (from involvement of the corticospinal tract). Caudal lesions affecting the facial nucleus or outflow tract cause ipsilateral facial weakness. Rostral lesions result in contralateral facial weakness. There may also be ipsilateral gaze paresis (paramedian pontine reticular formation or abducens nucleus, together comprising the *pontine gaze center*) or abducens paresis (sixth nerve outflow tract); internuclear ophthalmoplegia and limb and gait ataxia are often present. Contralateral impairment of

proprioception and discriminative touch is most prominent with caudal lesions. Rapid involuntary movements of the palate—so-called *palatal myoclonus*—has been attributed to involvement of the central tegmental tract; the involuntary movements may spread to include the pharynx, larynx, face, eyes, or respiratory muscles.

Midbrain syndromes are viewed as ventral (or peduncle), tegmental, and dorsal (including the collicular, pretectal, and tectal areas) (Figure C-9). Because the vertebral and basilar arteries themselves are usually the site of occlusion, pure forms of these stereotypic syndromes are infrequently encountered clinically. Unilateral ventral lesions cause Weber syn*drome*, characterized by ipsilateral paresis of adduction and vertical gaze and pupillary dilation (involvement of oculomotor nerve outflow tract) and contralateral face, arm, and leg paresis (corticospinal and corticobulbar tracts). Unilateral tegmental lesions cause Claude syndrome, characterized by oculomotor paresis (oculomotor nucleus) and contralateral ataxia and tremor (often referred to as rubral tremor but probably the result of damage to projections from the cerebellum to the thalamus). Lesions affecting both the peduncle and tegmentum produce combinations of oculomotor paresis, ataxia, and weakness (Benedikt syndrome). Dorsal midbrain lesions, which are infrequently vascular and rarely unilateral, cause Parinaud syndrome, characterized by impaired vertical gaze—especially upward (posterior commissure and the rostral interstitial nucleus of the median longitudinal fasciculus)—and loss of the pupillary light reflex (pretectal structures).

Because the vertebral and basilar arteries themselves are usually the site of occlusion, pure forms of these stereotypic syndromes are infrequently encountered clinically.

Bilateral brain stem lesions can be devastating. Paramedian infarction of the upper brain stem can destroy the reticular activating system and cause stupor or coma. Bilateral infarction of the rostral basis pontis destroys descending corticospinal and corticobulbar fibers, causing paralysis of all muscles except eye movements; if the tegmentum is spared such patients remain awake and communicate with their eyes (the locked-in state).

Infarction Can Be Restricted to the Cerebellum

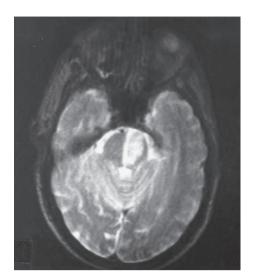

Infarcts of the inferior cerebellum, which has extensive vestibular connections, can cause vertigo, nausea, and nystagmus without other symptoms, suggesting disease of the inner ear or vestibular nerve. More superior cerebellar infarcts produce gait and ipsilateral limb ataxia.

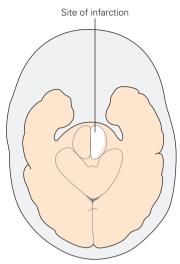

Table C-1 Syndromes of Brain Stem Infarction

	Symptoms	Structure involved
Medulla		
Lateral	Vertigo, nystagmus	Vestibular nuclei
	Ataxia of gait and ipsilateral limbs	Inferior cerebellar peduncle and cerebellum
	Decreased pain and temperature sensation on ipsilateral face	Spinal tract and nucleus of trigeminal nerve
	Decreased pain and temperature on contralateral body	Spinothalamic tract
	Dysphagia, hoarseness	Nucleus ambiguus
	Ipsilateral Horner syndrome	Descending sympathetic fibers
	Ipsilateral loss of taste	Nucleus solitarius
Medial	Contralateral hemiparesis	Corticospinal tract
	Ipsilateral tongue weakness	Hypoglossal nucleus and emerging fibers of N. XII
	Decreased proprioception and discriminative sensation on contralateral body	Medial lemniscus
Pons		
Lateral	Ataxia of gait and ipsilateral limbs	Middle cerebellar peduncle and cerebellum
	Decreased pain, temperature, and touch sensation on ipsilateral face	Primary sensory nucleus of trigeminal nerve
	Deafness, tinnitus	Cochlear nuclei
	Decreased pain and temperature sensation on contralateral body	Spinothalamic tract
	Ipsilateral jaw weakness	Trigeminal motor nucleus
	Ipsilateral Horner syndrome	Descending sympathetic fibers
Medial	Contralateral hemiparesis	Corticospinal tract
	Ipsilateral facial weakness	Facial nucleus and emerging fibers of N. VII
	Ipsilateral gaze paresis	Paramedian pontine reticular formation or abducens nucleus
	Ipsilateral abducens paresis	Abducens nucleus and emerging fibers of N. VI
	Internuclear ophthalmoplegia	Median longitudinal fasciculus
	Limb and gait ataxia	Nuclei and crossing cerebellar fibers of the basis pontis
	Decreased proprioception and discriminative sensation on contralateral body	Medial lemniscus
Midbrain ¹		
Ventral	Ipsilateral pupillary dilation and paresis of adduction and vertical gaze	Emerging fibers of oculomotor nerve
	Contralateral face weakness and hemiparesis	Corticobulbar and corticospinal tracts
Tegmental	Ipsilateral oculomotor paresis	Oculomotor nucleus
	Contralateral limb ataxia and tremor	Cerebellar projections to red nucleus and thalamus
Dorsal	Bilateral paresis of upward gaze and loss of pupillary light reflex (Parinaud syndrome)	Posterior commissure, rostral interstitial nucleus of the median longitudinal fasciculus, and pretectal structure

¹See Figure C–9.

Figure C–8 Magnetic resonance imaging shows a lesion (white highlight) in the ventral portion of one half of the pons. The lesion stops abruptly at the midline, suggesting unilateral occlusion of one or more paramedian vessels.

Infarction Can Affect the Spinal Cord

Vascular anatomy explains the characteristic pattern of spinal cord infarction (Figure C–10). Vessel occlusion is usually in a proximal segmental artery. Because of the anastomotic continuity of the posterior spinal arteries, infarction tends to be limited to the anterior spinal artery territory. Thus paraparesis or quadriparesis (corticospinal tracts), loss of bladder and bowel control, and loss of pain and temperature sensation below the lesion (spinothalamic tracts) are common; but proprioception and discriminative touch (dorsal columns) are spared.

If the cervical or lumbar spinal cord is involved, atrophic weakness of upper or lower extremity muscles (anterior horns) can occur. Because the anterior spinal artery gives off sulcal arteries that alternately enter the left and right halves of the spinal cord, infarction can sometimes produce a Brown-Séquard syndrome, with ipsilateral weakness and contralateral loss of pain and temperature sensation.

Diffuse Hypoperfusion Can Cause Ischemia or Infarction

Brain ischemia or infarction may accompany diffuse hypoperfusion (shock). In such circumstances the most vulnerable regions are often the border zones between large arterial territories and the end zones of deep penetrating vessels. Whatever the cause of reduced cerebral perfusion, signs tend to be bilateral. Paralysis and sensory loss may be present in both arms (from bilateral infarction of the cortex at the junction of the middle and anterior arterial supply, affecting the arm control area of the motor and sensory cortex).

Disturbed vision or memory may result (from infarction of the occipital or inferior temporal lobes at the junction of the middle and posterior cerebral arterial supply). There may also be ataxia (from cerebellar border zone infarction) or abnormal movements such as chorea or myoclonus (presumably from involvement

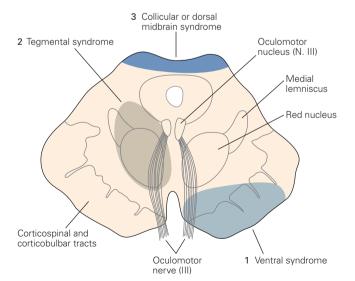

Figure C-9 The three midbrain syndromes. Syndromes of midbrain infarction are conveniently characterized as ventral (1), tegmental (2), or dorsal (3).

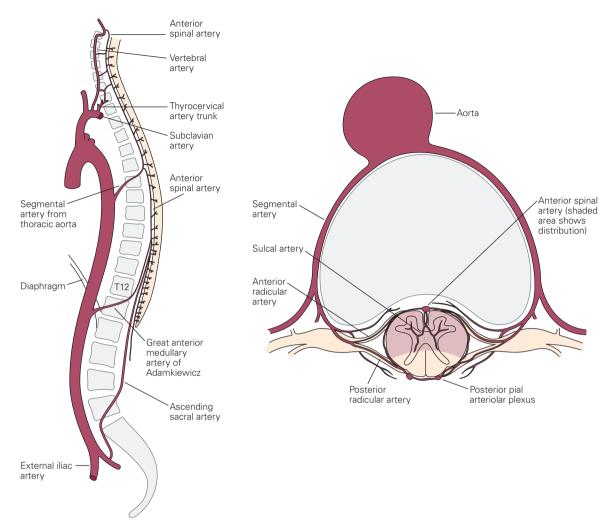

Figure C-10 Major sources of blood supply to the spinal cord. (Anterior spinal rami are not shown.)

of the basal ganglia). Such signs may exist alone or in combination and may be accompanied by aphasia or other cognitive disturbances.

Hypotension can also cause spinal cord infarction, most often upper thoracic, affecting either the territory of the anterior spinal artery or the border zone between the anterior and posterior spinal arteries.

Cerebrovascular Disease Can Cause Dementia

Cerebral infarction causes dementia by a number of mechanisms:

1. Infarcts may be critically located. For example, thalamic or inferomedial temporal damage (posterior cerebral artery, usually bilateral) can cause amnesia; hemispheric convexity damage (middle

- cerebral artery) can cause cognitive or behavioral impairment not explained by disruption of language or spatial discrimination; and bilateral inferomedial frontal lobe damage (anterior cerebral artery) can cause abulia and impaired memory.
- Multiple scattered infarcts, none sufficient to cause significant cognitive loss, can produce additive effects culminating in dementia. In such patients at least 100 cc of brain volume has usually been destroyed.
- 3. Small vessel disease, affecting especially the deep cerebral white matter, can cause either scattered lacunes or more diffuse ischemic lesions. When such lesions are severe enough to cause dementia, there is often altered behavior, pseudobulbar palsy, pyramidal signs, disturbed gait, and urinary incontinence.

The Rupture of Microaneurysms Causes Intraparenchymal Stroke

The two most common causes of hemorrhagic stroke, hypertensive intraparenchymal hemorrhage and rupture of a saccular aneurysm, tend to occur at particular sites and to cause recognizable syndromes. Hypertensive intracerebral hemorrhage is the result of damage to the same small penetrating vessels that, when occluded, cause lacunes; in the case of hemorrhage the damaged vessels develop weakened walls (Charcot-Bouchard microaneurysms) that eventually rupture. The most common sites are the putamen, thalamus, pons, internal capsule and corona radiata, and cerebellum. Large diencephalic hemorrhages tend to cause stupor and hemiplegia and have a high mortality rate.

With putamenal hemorrhage (Figure C–11) the eyes are usually deviated ipsilaterally (because of disruption of capsular pathways descending from the

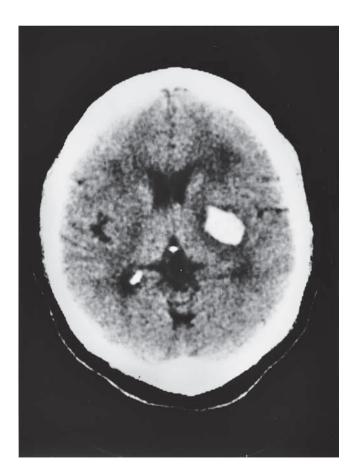

Figure C-11 Computed tomography scan showing hemorrhage (white area) in the putamen. (Reproduced, with permission, from Allan J. Schwartz.)

frontal eye field), whereas with thalamic hemorrhage (Figure C–12) the eyes tend to be deviated downward and the pupils may not react to light (because of involvement of midbrain pretectal structures essential for upward gaze and pupillary light reactivity). Small hemorrhages may not impair alertness, and with small thalamic hemorrhages sensory loss may exceed weakness. Moreover, computerized tomography reveals that small thalamic hemorrhages can cause aphasia when on the left and hemineglect when on the right.

Pontine hemorrhage, unless quite small, usually causes coma (by disrupting the reticular activating system) and quadriparesis (by transecting the corticospinal tracts). Eye movements, spontaneous or reflex (eg, to ice water in either external auditory canal) are absent, and pupils are pinpoint in size, reflecting transection of descending sympathetic pathways. Pupillary light reactivity is usually preserved, however, for the pathway mediating this reflex, from retina to midbrain, is intact. Respirations may be irregular, presumably because the caudal reticular formation is involved. These strokes are nearly always fatal.

Cerebellar hemorrhage, which tends to occur in the region of the dentate nucleus, typically causes a sudden inability to stand or walk (astasia-abasia), with ipsilateral limb ataxia. There may be ipsilateral abducens palsy, or horizontal gaze palsy, or facial weakness, presumably from pontine compression. Long-tract motor and sensory signs are usually absent, however. As swelling increases, further brain stem damage may cause coma, ophthalmoplegia, miosis, and irregular respiration, with fatal outcome.

The Rupture of Saccular Aneurysms Causes Subarachnoid Hemorrhage

Saccular aneurysms (not to be confused with hypertensive Charcot-Bouchard microaneurysms) are most often found at the junction of the anterior communicating artery with an anterior cerebral artery, the junction of a posterior communicating artery with an internal carotid artery, and the first bifurcation of a middle cerebral artery in the sylvian fissure. Each aneurysm, upon rupture, tends to cause not only sudden severe headache but also a characteristic syndrome. By producing a hematoma directly over the oculomotor nerve as it traverses the base of the brain, a ruptured posterior communicating artery aneurysm often causes ipsilateral pupillary dilation with loss of light reactivity. A middle cerebral artery aneurysm may, by either hematoma or secondary infarction, cause a clinical picture resembling that of middle cerebral artery occlusion. After rupture of an anterior communicating

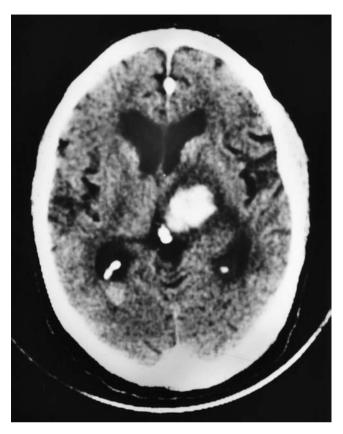

Figure C–12 Computed tomography scan showing thalamic hemorrhage (white area) surrounded by edema or infarction (dark zone). (Reproduced, with permission, from Allan J. Schwartz.)

artery aneurysm, there may be no focal signs but only decreased alertness or behavioral changes.

Posterior fossa aneurysms most often occur at the rostral bifurcation of the basilar artery or at the origin of the posterior inferior cerebellar artery. They cause a variety of cranial nerve and brain stem signs. Rupture of an aneurysm at any site may cause abrupt coma; the reason is uncertain but may be related to sudden increased intracranial pressure and functional disruption of vital pontomedullary structures.

Stroke Alters the Vascular Physiology of the Brain

After a stroke, cerebral blood flow and cerebrovascular responses to changes in blood pressure or arterial gases are altered. There may be vasomotor paralysis

with loss of autoregulation in response to blood pressure changes and then blunted responses to alterations in arterial O₂ or CO₂. This kind of physiological abnormality is especially likely in brain areas that are ischemic but not yet infarcted; such an area often surrounds acutely infarcted brain tissue and is called the *ischemic penumbra*. Lowered blood pressure in this setting can, by critically reducing perfusion in the penumbra, convert ischemia to infarction. The use of cerebral vasodilators can also produce an unintended response, increasing cerebral blood flow in regions distant from the ischemic region without affecting vessels within the ischemic region. Blood may therefore be shunted from ischemic to normal brain.

Strategies for restoring cerebral perfusion in patients with acute ischemic stroke (for example, giving recombinant tissue-type plasminogen activator to degrade the clot causing the infarction) are based on the assumption that an ischemic penumbra represents salvageable tissue, even if infarction within it does not.

To FUNCTION OPTIMALLY, NEURONS of the central nervous system and their supporting glia require a highly specialized environment. The fluids that bathe the central nervous system's interstitial and cerebrospinal compartments are regulated by

the blood-brain and blood-cerebrospinal fluid (CSF) barriers. Evidence for these barriers was first obtained in the 19th century when it was observed that acidic vital dyes stain the brain if the dye is injected into the cerebrospinal fluid but not if injected into the blood stream.

The interstitial fluid in the brain and the cerebrospinal fluid in the intraventricular and subarachnoid spaces are separately compartmentalized. Homeostasis of these fluid compartments and ultimately the intracellular compartment of brain cells is regulated to a great degree by the blood-brain and blood-CSF barriers (Figure D–1). Endothelial cells of the cerebral microvasculature form the blood-brain barrier that regulates the movement of molecules between the blood and interstitial fluid compartments. Epithelial cells of the choroid plexus produce the cerebrospinal fluid and regulate its composition.

These barriers exclude toxic substances and protect neurons from circulating neurotransmitters such as norepinephrine and glutamate, the blood levels of which can increase greatly after a meal or in response to stress. The selective exclusion by the blood–brain barrier results primarily from specialized anatomical properties of the endothelial cells that limit the passive diffusion of water-soluble substances from the blood into the interstitial and cerebrospinal fluid compartments. As a result, many metabolites required for brain growth and function must be transported selectively across the brain endothelial and choroid epithelial cell surfaces. Specific transporters deliver energy substrates, essential amino acids, and peptides to the brain and remove metabolites.

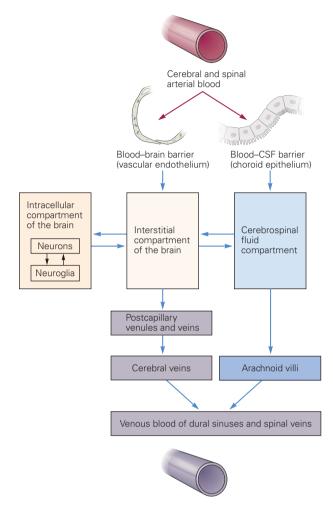

Figure D–1 Relationships between intracranial fluid compartments and the blood–brain and blood–cerebrospinal fluid (CSF) barriers. The tissue elements indicated in parentheses form the barriers. Arrows indicate the direction of fluid flow under normal conditions. (Adapted, with permission, from Carpenter 1978.)

The Blood-Brain Barrier Regulates the Interstitial Fluid in the Brain

Distinctive Properties of the Endothelial Cells of Brain Capillaries Account for the Blood-Brain Barrier

The small blood vessels of the brain are composed primarily of endothelial cells that continuously line the vessel luminal surface. On the abluminal side the endothelial cells are associated with pericytes, smooth muscle-like cells imbedded within the basement membrane of microvessels. Perivascular astrocytes extend processes that ensheathe most of the abluminal

microvessel surface to form a microvessel-astroglial complex (Figure D–2). The endothelial cells and their extensive intercellular junctions are the principal component of the barrier (Figure D–3).

In capillaries of peripheral organs and in the relatively few brain capillaries that do not contribute to the barrier (eg, those of the circumventricular organs), blood-borne polar molecules diffuse across vessel walls by multiple mechanisms. This diffusion occurs through spaces between endothelial cells, through specialized cytoplasmic fenestrations, or by fluid-phase or receptor-mediated endocytosis.

Fluid-phase endocytosis is a relatively nonspecific process by which endothelial cells (and most other cells) engulf and then internalize molecules encountered in the extracellular space by vesicular endocytosis. Receptor-mediated endocytosis is a specific process in which a ligand binds to a membrane receptor on the external surface of a cell, is internalized by means of clathrin-coated vesicles, and is transported across the cell membrane. Once within the cell the vesicle may traverse the cell, fuse with the cell membrane on the opposite cell surface and release its contents to the extracellular space, or fuse with an intracellular endosome and release its contents.

Endothelial cells of blood–brain barrier vessels are relatively deficient in vesicular transport and they are also nonfenestrated. Instead they are interconnected by complex arrays of tight junctions (Figure D–3B), which block diffusion across vessel walls. All generic endothelial cells are interconnected by a modest number of tight junctional complexes and normally have low transendothelial resistance (5–10 ohm-cm²). In the vessels of the blood–brain barrier, however, extensive arrays of tight junctions generate high transendothelial resistance (2,000 ohm-cm²), excluding particles as small as K⁺ ions (Figure D–4).

Tight Junctions Are a Major Feature of the Anatomical Blood–Brain Barrier Composition and Structure

Tight junctions of the blood-brain barrier are composed of three principal transmembranous proteins—claudins, occludins, and junctional adhesion molecules—as well as numerous cytoplasmic accessory proteins (Figure D–5).

Claudin (~22 kDa) has four transmembrane domains and forms the backbone of tight junctional complexes. Of the more than 20 members of the claudin gene family, isoforms 1 and 5 are expressed at the junctions of the blood–brain barrier. Occludin (~65 kDa) is a tight junctional protein, also has four transmembrane

domains, and is recruited to junctional complexes by claudins. Claudins and occludins interact intimately at the junctional membrane to influence junctional complexity and tightness. Junctional adhesion molecules (JAMs) are located lateral to the claudins and occludins and mediate cell-cell adhesive interactions required for junctional assembly. JAMs also play an important role in the transmigration of inflammatory cells across barrier endothelial cells.

Numerous accessory proteins positioned on the cytoplasmic side of tight junctions mediate interactions between the transmembrane junctional and cytoskeletal proteins and modulate dynamic junctional properties. The zona occludin proteins link the occludins and claudins to the actin cytoskeleton (Figure D–5). They also form a scaffold for other regulatory proteins such as cingulin, a myosin-like protein, and AF-6, a target of the small G protein Ras. It is currently believed that changes in protein-protein interactions at the cytoplasmic junctional—cytoskeletal interface, resulting from gene transcription and protein phosphorylation events, modulate tight junction structure and function.

The Blood-Brain Barrier Is Permeable in Three Ways

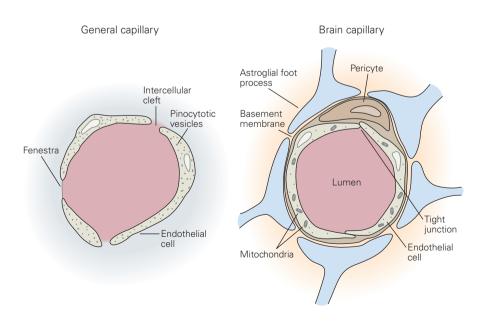

Normal development and brain function require many substances that must cross brain microvessels. Entry into the brain is achieved primarily in three ways: (1) by diffusion of lipid soluble substances, (2) by facilitative and energy-dependent receptor-mediated transport of specific water-soluble substances, and (3) by ion channels.

Diffusion of Lipid-Soluble Substances

The brain is separated from the blood only by the large surface of endothelial cell membrane (approximately 180 cm²/g in gray matter). This membrane permits the efficient exchange of lipid-soluble gases such as oxygen (O₂) and carbon dioxide (CO₂), an exchange limited only by the surface area of the blood vessels and by cerebral blood flow. Barrier vessels are impermeable to molecules with poor lipid-solubility such as mannitol. The permeability coefficient of the blood–brain barrier for many substances is directly proportional to the lipid-solubility of the substance as measured by the oil–water partition coefficient (Figure D–6).

An example of the relationship of permeability and lipid-solubility is the correlation between the relative abuse potential of psychoactive drugs such as nicotine and heroin and their lipid-solubility. Increasing the lipid-solubility of drugs enhances their delivery to the brain. Drugs with great lipid-solubility, however, are poorly soluble in blood and bind to serum albumin

Figure D-2 Ultrastructural features of endothelial cells of brain capillaries and general (systemic) capillaries. The endothelial cells of brain barrier capillaries are relatively lacking in pinocytotic vesicles, contain an increased number of mitochondria to support energy-dependent transport properties, and are interconnected by very complex interendothelial tight junctions (see Figure D-5). These anatomical features in conjunction with specific transport systems (see Figure D-7) result in highly selective transport of water-soluble compounds across the barrier endothelium. Astroglial foot processes almost completely surround the brain capillaries and are thus believed to influence barrier-specific endothelial differentiation. In contrast, systemic capillaries have interendothelial clefts, fenestrae, and prominent pinocytotic vesicles. These features of systemic capillaries allow relatively nonselective diffusion across the capillary wall. (Reproduced, with permission, from Goldstein and Betz 1986.)

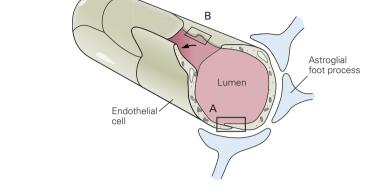

Figure D-3 Tight junctions between endothelial cells are the basis of the anatomical bloodbrain barrier.

A. 1. When injected into arteries that supply the brain, the electrondense tracer horseradish peroxidase is easily visualized within the brain vessel lumens (dark staining at top) but is excluded from entering the brain by interendothelial tight junctions (TJ). The luminal space appears at the top of the electron micrographs in both 1 and 2. (Reproduced, with permission, from Reese and Karnovsky 1967.) 2. When injected into the subarachnoid space, horseradish peroxidase readily diffuses between the perivascular astroglial foot processes and across the abluminal basement membrane (BM) but fails to penetrate the interendothelial tight junction. (Reproduced, with permission, from Brightman and Reese 1969.)

B. This freeze-fracture photomicrograph of isolated brain microvessels shows complex arrays of interendothelial tight junctions (TJ). (Reproduced, with permission, from Shivers et al. 1984.)

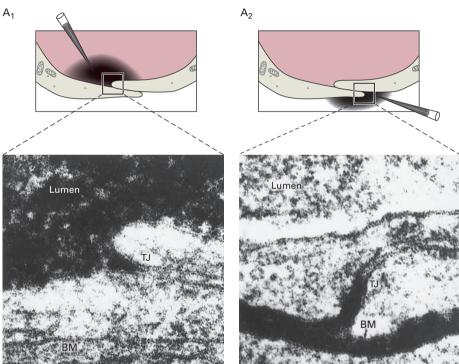

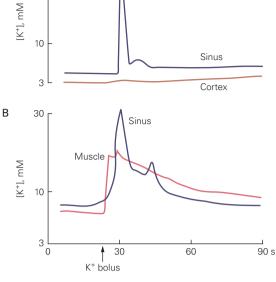

Figure D–4 Time course of K^+ entry into tissue extracellular fluid following arterial injection. The time course of K^+ entry into the cerebral cortex and neck muscle is compared to the cerebral venous outflow in the sagittal sinus following bolus injection of potassium chloride (KCI) in the aortic arch.

A. In the cerebral cortex the $K^{\scriptscriptstyle +}$ concentration remains essentially unchanged because of the blood–brain barrier to ions.

B. In the neck muscle K^+ diffuses rapidly across nonbarrier vessels into the extracellular space of the muscle. (Reproduced, with permission, from Hansen et al. 1977.)

Figure D–5 Protein interactions at the tight junctions between barrier endothelial cells. Occludin, claudin, and junctional adhesion molecules (JAM) are membrane-spanning junctional proteins. Claudins on adjacent endothelial cells bind homotypically and mediate interendothelial adhesive interactions. Occludins interact with claudins to enhance and modulate interendothelial permeability. JAMs localize to the periphery of

junctional complexes and mediate inflammatory cell transmigration across barrier endothelial cells. The cytoplasmic accessory proteins represented by zona occludins (ZO-1, ZO-2, and ZO-3), AF-6, and 7H6, regulate the interaction of junctions with cytoskeletal components and modulate junction function via interactions with signal transduction proteins in the membrane and cytoplasm. (Adapted, with permission, from Huber et al. 2001.)

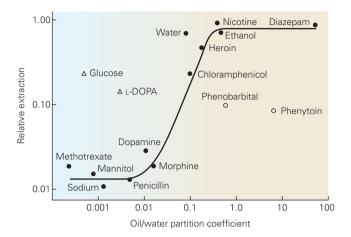

Figure D–6 The oil–water partition coefficient correlates with brain uptake of many compounds. The coefficient is an index of lipid solubility. Brain uptake of a substance is determined by comparing the extraction of the substance relative to a highly permeable tracer during a single passage through the cerebral circulation. In general, compounds with higher coefficients have a greater uptake in the brain. Uptake of the anticonvulsants phenobarbital and phenytoin is lower than predicted from their lipid-solubility partly because of their binding to plasma proteins. This explains why the onset of anticonvulsant activity from these agents is slower than that of diazepam. Uptake of glucose and L-dihydroxyphenylalanine (L-DOPA) is greater than indicated by their lipid solubility because specific carriers facilitate their transport into the brain capillary. (Reproduced, with permission, from Goldstein and Betz 1986.)

protein, properties that reduce delivery to the brain. Lipid-solubility is not an accurate indicator of the permeability of some hydrophilic substances, such as glucose and vinca alkaloids, because of the presence of selective endothelial transport or enzyme systems that increase or inhibit permeability.

Facilitative and Energy-Dependent Transport

Most substances that cross the blood–brain barrier are not lipid-soluble and therefore enter and leave the brain by specific transport systems (Figure D–7). Because the brain uses glucose almost exclusively as its source of energy, the hexose transporter (glucose transporter isotype-1, Glut1) of the barrier endothelial cells is abundant.

Like other transporters Glut1 consists of 12-transmembrane segments. It is a facilitative, saturable, and stereospecific transporter that functions at both the luminal and abluminal endothelial cell membranes. Because it is not energy-dependent, it cannot move glucose against a concentration gradient. In fact, the

net flux of glucose is driven by the higher concentration of glucose in the plasma. More than 99% of the glucose that enters barrier endothelial cells is shuttled across for use by neurons and glia.

Monocarboxylic acids such as β -hydroxybutyrate serve as the brain's primary energy source during early development in suckling neonates and in response to starvation in mature animals. These acids are transported across the barrier endothelial cells by the monocarboxylic acid transporter-1 (MCT1).

Amino acids are transported across barrier endothelial cells primarily by three distinct carrier systems. These systems (L, A, and ASC) were initially characterized by their different patterns and mechanisms of transport, and by their preference for different amino acid analogs. The *L-system* preferentially transports large neutral amino acids with branched or ringed side chains such as leucine and valine. This Na⁺-independent, facilitative transport system is located at luminal and abluminal endothelial cell membranes. It also transports L-DOPA L-dihydroxyphenylalanine), the dopamine precursor that is the mainstay for treating Parkinson disease.

The *A-system* preferentially transports glycine and neutral amino acids with short linear or polar side chains, such as alanine or serine. Unlike the L-system this carrier is Na⁺-dependent, and pumps amino acids down a Na⁺ gradient that is maintained by Na⁺-K⁺-adenosine triphosphatase (ATPase), an ionic pump that uses ATP.

The *ASC-system* is also an energy-dependent and Na⁺-dependent transporter that preferentially recognizes alanine, serine, and cysteine. A-system and ASC-system expression and function are localized at the abluminal endothelial cell surface. As a consequence of this localization these carriers are the primary means of transport of small neutral amino acids out of brain up a concentration gradient.

Another transport system found to be most abundant in brain barrier microvessels belongs to a family of ATP-binding cassette transporters (ABC transporters), a large family of transmembrane proteins expressed in many cell types. The first member of this family was identified for the ability to impart multiple drug resistance (MDR) to tumor cells. The MDR transporter limits the entry into cells of a wide range of natural and synthetic hydrophobic toxins (eg, vinca alkaloids, actinomycin-D) and therapeutic compounds (eg, cyclosporin). The ability of MDR transporters to pump certain steroid hormones suggests a physiologic role. MDR transporters are expressed by barrier endothelial cells but not by endothelial cells of most other tissues. This explains why MDR substrates do not readily cross the blood-brain barrier. Mice genetically engineered to

lack MDR1a gene expression are much more sensitive than wild-type controls to centrally acting toxic compounds, indicating that MDR gene expression at the blood-brain barrier protects the brain from circulating neurotoxins.

Ion Channels and Exchangers

Specific ion channels and ion transporters mediate electrolyte movement across the blood–brain barrier. A nonselective luminal ion channel that is inhibited by both amiloride and atrial natriuretic peptide has been revealed in both in vivo studies of transport across brain microvessels and patch-clamp studies of cultured brain endothelial cells. Na⁺/H⁺ and Cl⁻/bicarbonate (HCO₃⁻) exchangers also appear to function at the luminal membrane.

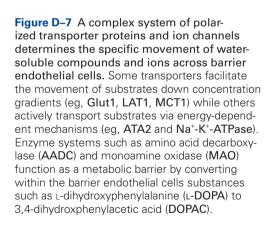

The abluminal membrane of brain endothelial cells has a relatively high concentration of Na^+-K^+-ATP ase that pumps K^+ from the interstitial fluid into

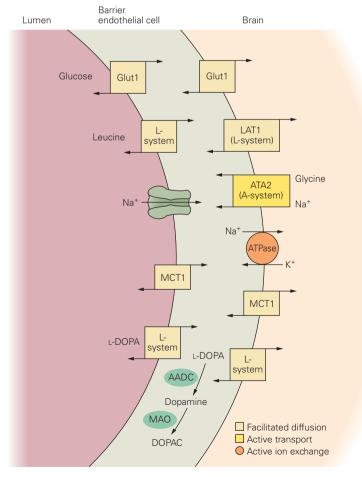

the endothelial cell and pumps Na^+ out of the cell. This ion exchange uses ATP energy. In conjunction with K^+ channels in astrocytes, this abluminal endothelial pump may play an important role in removing extracellular K^+ released during neuronal activity (see Chapter 6).

Endothelial Enzyme Systems Form a Metabolic Blood-Brain Barrier

Transport systems and carriers are not the only mechanisms for regulating the composition of the interstitial fluid. Certain enzyme systems specific to the bloodbrain barrier are also important. The first recognized and best characterized is the barrier to L-DOPA.

Plasma L-DOPA enters brain endothelial cells by means of the L-system amino acid transporter. The relatively large amounts of DOPA decarboxylase and monoamine oxidase in barrier endothelial cells rapidly metabolize L-DOPA to 3,4-dihydroxyphenylacetic acid, thereby inhibiting the entry of L-DOPA to brain

(Figure D–7). This explains why effective therapy for Parkinson disease requires that L-DOPA be given together with an inhibitor of DOPA decarboxylase.

Other blood-borne amines, including catecholamines, are inactivated by monoamine oxidases of the barrier endothelium. Another barrier enzyme, γ -glutamyl transpeptidase, detoxifies glutathione-bound compounds and vasoactive leukotrienes.

Some Areas of the Brain Lack a Blood-Brain Barrier

Not all cerebral blood vessels are impermeable. Leaky structures include the posterior pituitary and the circumventricular organs: the area postrema, subfornical organ, laminar terminalis, subcommissural organ, and median eminence.

The absence of the blood-brain barrier in these regions is consistent with their physiologic functions. Neurosecretory products of the posterior pituitary have to pass efficiently across endothelial cells into the circulation. The subfornical organ is a chemoreceptor-rich area that monitors the blood level of angiotensin II to regulate water balance and other homeostatic functions.

These regions are isolated from the rest of the brain by specialized ependymal cells called *tanycytes* located along the ventricular surface close to the midline. The tanycytes are coupled by tight junctions and prevent free exchange between the circumventricular organs and the cerebrospinal fluid.

Brain-Derived Signals Induce Endothelial Cells to Express a Blood-Brain Barrier

The developing brain expresses the cellular and molecular signals that induce endothelial expression of the blood–brain barrier phenotype. The neural anlagen of the brain is vascularized early in development through the invasion of proliferating vessels derived from an extraneural vascular plexus. These perineural vessels are composed of fenestrated endothelial cells that have no blood–brain barrier properties. The fenestrations are lost soon after the endothelial cells penetrate neural tissue. The subsequent expression of different bloodbrain barrier properties on the endothelium occurs gradually, consistent with a maturational cascade.

The brain parenchymal signals that induce endothelial barrier formation are not known. Of the principal cell types within the brain, astrocytes are thought to be particularly important for this function because of their intimate association with the abluminal surface of brain blood vessels and from experimental evidence in blood–brain barrier model systems.

Diseases Can Alter the Blood-Brain Barrier

A variety of pathological situations are associated with altered blood-brain barrier function. Many brain tumors, especially highly malignant ones, contain vessels with poorly developed blood-brain barriers. Such vessels are excessively leaky and lack the differentiated transport properties of normal blood-brain barrier vessels. The abnormal permeability accounts for the accumulation of interstitial fluid (ie, vasogenic edema) commonly associated with brain tumors. The abnormal properties of tumor endothelial cells are presumably due to either the absence of normal interactions between astrocytes and capillaries or by the secretion of growth factors and cytokines by tumor cells. Factors secreted by tumors that enhance vessel proliferation and permeability include vascular endothelial growth factor (VEGF), hepatocyte growth factor/scatter factor (HGF/SF), and matrix metalloproteinases.

The blood-brain barrier is also altered in bacterial meningitis. The barrier is normally impermeable to antibiotics such as penicillin. Bacterial meningitis, abscesses, and their associated inflammatory responses cause partial breakdown of the blood-brain barrier. This barrier response appears to be mediated in part by the accumulation of vasoactive eicosanoids; inflammatory cytokines such as tumor necrosis factor, interleukins, and macrophage chemoattractant protein-1; and matrix metalloproteinases that degrade capillary basement membranes. This barrier dysfunction accounts for many adverse neurological effects of meningitis but it also enhances the delivery of antibiotics that inefficiently penetrate across an intact barrier.

Because development and function of the normal brain are closely linked to specific anatomical, biochemical, and transport properties of the blood–brain barrier, specific defects in genes that code for barrier endothelial proteins might account for inherited brain disorders. The first disorder of blood–brain barrier transport to be recognized involves insufficient endothelial transport of glucose because of sporadic mutations in the *glut1* gene causing Glut1 haploinsufficiency. Patients with this syndrome are normal at birth but soon develop poorly controlled seizures, diminished brain growth, and mental retardation in association with a substantially diminished concentration of cerebrospinal fluid glucose.

Cerebrospinal Fluid Is Secreted by the Choroid Plexuses

Cerebrospinal fluid is secreted in the cerebral ventricles mainly by the choroid plexuses (Figure D-8A),

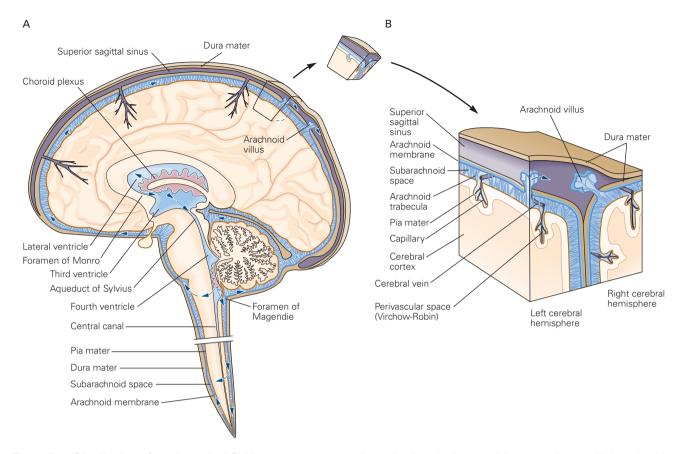

Figure D-8 Distribution of cerebrospinal fluid.

A. Sites of formation, circulation, and absorption of cerebrospinal fluid (CSF). All spaces containing CSF communicate with each other. Choroidal and extrachoroidal sources of the fluid exist within the ventricular system, which is lined by permeable ependymal cells. The CSF circulates to the subarachnoid space and is absorbed into the venous system via the arachnoid villi. Arachnoid villi adiacent to the spinal roots supplement the

absorption into the intracranial venous sinuses. (Adapted, with permission, from Fishman 1992.)

B. The subarachnoid space is bounded externally by the arachnoid membrane and internally by the pia mater, which penetrates the surface of the brain along with blood vessels to form Virchow-Robin spaces. (Adapted, with permission, from Carpenter 1978.)

capillary networks that are surrounded by cuboidal or columnar epithelium. The CSF flows from the lateral ventricles through the interventricular foramina of Monro into the third ventricle. From there it flows into the fourth ventricle through the cerebral aqueduct of Sylvius and then through the foramina of Magendie and Luschka into the subarachnoid space. The subarachnoid space lies between the arachnoid and the pia mater, which, together with the dura mater, form the three meningeal layers that cover the brain (Figure D–8B). Within the subarachnoid space, fluid flows down the spinal canal and also upward back over the convexity of the brain (Figure D–8A).

The CSF flowing over the brain extends into the sulci and the depths of the cerebral cortex in extensions

of the subarachnoid space along blood vessels called the Virchow-Robin spaces. Small solutes diffuse freely between the interstitial fluid and the CSF in these perivascular spaces and across the ependymal lining of the ventricular system, facilitating the movement of metabolites from deep within the hemispheres to cortical subarachnoid spaces and the ventricular system. This flow of interstitial fluid across the ependymal surface into the ventricular system (extrachoroidal cerebrospinal fluid production) is believed to account for at most a small percentage of total CSF production.

The total volume of CSF is estimated to be approximately 140 mL. Under normal conditions the lateral and third ventricles contain approximately 12 mL and the spinal subarachnoid space approximately 30 mL as

measured by computed tomography. The remaining 100 mL is in the subarachnoid space and the major cisterns of the brain (eg, cisterna magna, mesencephalic cistern).

The CSF is absorbed through the arachnoid granulations and villi. Arachnoid granulations consist of clusters of villi that typically form visible herniations of the arachnoid membrane through the dura and into the lumen of the superior sagittal sinus and other venous structures (Figure D–8). The villi themselves are visible microscopically and positioned between the CSF and venous blood. Cells of the villus membrane contain vacuoles that transport fluid from one side of the cell to the other (Figure D–9).

The granulations appear to function as valves that allow one-way flow of CSF from the subarachnoid spaces into venous blood. This one-way flow of CSF is sometimes called bulk flow because all constituents of CSF leave with the fluid, including small molecules, proteins, microorganisms, and red blood cells. The rate of formation of CSF in adults is 0.35 mL per minute or approximately 500 mL per day, so that the entire volume of CSF is turned over three or four times a day.

Cerebrospinal Fluid Has Several Functions

The CSF communicates with brain interstitial fluid and therefore helps maintain a constant extracellular environment for neurons and glia. The one-way flow of CSF from the ventricular system into the subarachnoid space and into the venous sinuses is a major route for removing potentially harmful brain metabolites.

The CSF also provides a mechanical cushion to protect the brain from impact with the bony calvarium when the head moves. By its buoyant action the CSF allows the brain (average weight 1400 g) to float, thereby reducing its effective weight in situ to less than 50 g.

The CSF may also serve as a lymphatic system for the brain and as a conduit for polypeptides that are secreted by hypothalamic neurons and act at remote sites in the brain. The pH of CSF affects both pulmonary ventilation and cerebral blood flow, another example of the homeostatic role of CSF.

Epithelial Cells of the Choroid Plexuses Account for the Blood-Cerebral Spinal Fluid Barrier

The choroid plexuses are structurally similar to the distal and collecting tubules of the kidney, using capillary filtration and epithelial secretory mechanisms to maintain the chemical stability of the CSF. The capillaries that traverse the choroid plexuses are freely permeable to

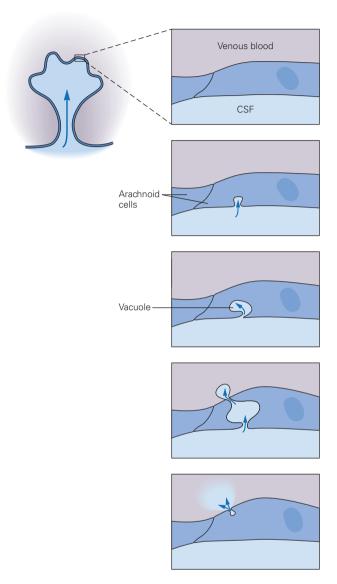

Figure D-9 Transport of cerebrospinal fluid within the arachnoid villi is achieved by giant vacuoles in the arachnoid cells. This mechanism could account for the one-way bulk flow of CSF from the subarachnoid space to the venous system. Some vacuoles are large enough to encompass red blood cells. (Adapted, with permission, from Fishman 1992.)

plasma solutes. A barrier exists, however, at the choroid epithelial cells. The transport and exchange of substances by the choroid plexuses are bidirectional, accounting for both continuous production of CSF and active transport of metabolites out of the central nervous system into the blood (Figure D–10).

The cerebrospinal and extracellular fluids of the brain are in a steady state under normal physiological

circumstances. The concentrations of K^+ , Ca^{2+} , bicarbonate, and glucose in the CSF are lower than in blood plasma, and CSF is also more acidic (Table D–1). These differences are a result of regulation of the constituents of CSF by active transport at the choroid plexus epithelium. Under normal conditions blood plasma and CSF are in osmotic equilibrium, because water follows the osmotic gradient that is created by active transport of solutes.

Choroid Plexuses Nurture the Developing Brain

The choroid plexuses appear as epithelial invaginations soon after neural tube closure where the lateral, third, and fourth ventricles will eventually form. They become vascularized and begin producing CSF before the brain becomes well vascularized. The ultimate vascularity of the choroid plexuses is high. In the mature

rat blood flow per gram of tissue is as much as fivefold higher in the choroid plexus than in cerebral cortex.

Production of CSF during early brain development is believed to have multiple functions. The hydrodynamic and pressure effects of CSF production may specifically influence the developing brain's three-dimensional shape and laminar organization. The CSF may be a source of nutrition for the developing prevascularized brain, as the choroid epithelial cells deliver substances from blood to the CSF for the developing brain. Initially this blood-to-CSF transfer occurs relatively nonspecifically through a transcellular tubular-cisternal endoplasmic reticular system. It becomes more selective as the choroid epithelial cells differentiate to create a mature blood-CSF barrier. The choroid epithelial cells also synthesize and secrete proteins that may have paracrine effects on the development of neighboring neuroepithelial cells.

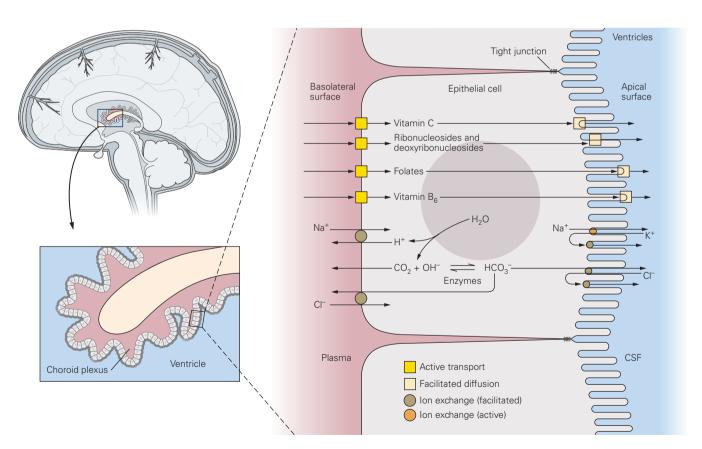

Figure D–10 The blood–cerebral spinal fluid barrier. The flow of molecules across the blood–CSF barrier is regulated by several mechanisms in the epithelial cells of the choroid plexus. Some micronutrients such as vitamin C are transported into epithelial cells by an energy-dependent active transporter located at the basolateral membrane and released into the CSF

at the apical surface by facilitated diffusion, which requires no energy. Essential ions are also exchanged between CSF and blood plasma. Transport of an ion in one direction is linked to the transport of a different ion in the opposite direction, as in the exchange of Na⁺ ions for K⁺ ions. (Adapted, with permission, from Spector and Johanson 1989.)

Table D-1 Comparison of Serum and Cerebrospinal Fluid

	CSF*	Serum
Water content (%)	99	93
Protein (mg/dL)	35	7000
Glucose (mg/dL)	60	90
Osmolarity (mOsm/L)	295	295
$Na^+(mEq/L)$	138	138
$K^{+}(mEq/L)$	2.8	4.5
Ca^{2+} (mEq/L)	2.1	4.8
Mg^{2+} (mEq/L)	0.3	1.7
$Cl^{-}(mEq/L)$	119	102
pH	7.33	7.41

*Average or representative values.

Increased Intracranial Pressure May Harm the Brain

In considering the factors that regulate intracranial pressure, the cranium and spinal canal should be regarded as a closed system. According to the Monro-Kellie doctrine, an increase in the volume of any one of the contents of the calvarium—brain tissue, blood, CSF, or other brain fluids—will increase intracranial pressure because the bony calvarium rigidly fixes the total cranial volume. Mass lesions and their associated interstitial edema commonly increase intracranial pressure.

Changes in arterial and intracranial venous pressures may also influence intracranial pressure by their actions on intracranial blood volume and CSF dynamics. Acute changes in arterial or venous pressures can change intracranial pressure dramatically. Chronic changes may be compensated by several mechanisms, including venous collateralization and increased absorption or decreased formation of CSF.

Cerebrospinal fluid pressure is ordinarily measured by lumbar puncture. With the patient lying sideways (lateral decubitus position), a needle is inserted between the fourth and fifth lumbar vertebrae and into the lumbar subarachnoid space. Because the spinal cord extends only to the first lumbar vertebra, there is no risk of injuring the spinal cord. When the CSF flows freely through the needle, the hub of the needle is attached to a manometer, and the fluid is allowed to rise. The normal pressure is 65 to 195 mm CSF (or water), or 5 to 15 mm Hg.

In using the lumbar CSF pressure as a guide to intracranial pressure, it is assumed that pressures are equal throughout the neuraxis. Normally this is reasonable; but in many diseases (eg, brain tumor or obstruction of CSF pathways) this may not be true. For this reason, and also because the lumbar needle cannot be left in place for prolonged periods, catheters are sometimes inserted into the lateral ventricles to measure pressure there (Figure D–11).

Equally effective are pressure-sensitive transducers that can be inserted under the skull in the epidural or subarachnoid space for continuous monitoring of intracranial pressure. Continuous monitoring has the advantage of identifying waves of transiently elevated intracranial pressure that can occur in certain disorders, such as normal pressure hydrocephalus.

Brain Edema Is an Increase in Brain Volume Because of Increased Water Content

Brain edema may be local (eg, from a surrounding contusion, infarct, or tumor) or generalized. The brain is divided into compartments by relatively noncompliant membranes. Local brain edema may cause herniation of brain tissue across these membranes. Specific examples include herniation of the cingulate gyrus across the falx cerebri, temporal lobe uncus across the cerebellar tentorium, or cerebral cortex outward through calvarial defects after surgery.

Vasogenic edema is the most common form of brain edema. It is attributed to increased permeability of brain capillary endothelial cells, which increases the volume of the extracellular fluid. White matter is generally affected more than gray because of the tendency of edema fluid to accumulate along tracts of white matter. Vasogenic edema is most easily visualized using magnetic resonance imaging. Pathological increases in permeability of the blood–brain barrier also can be visualized by computerized tomography and magnetic resonance imaging after intravenous administration of contrast agents that selectively enter the brain through the affected vessels

Cytotoxic edema refers to the intracellular swelling of injured neurons, glia, and endothelial cells. It occurs in hypoxia from asphyxia or global cerebral ischemia after cardiac arrest because failure of the ATP-dependent Na⁺-K⁺ pump allows Na⁺, and therefore water, to accumulate within cells. Another cause of cytotoxic edema is water intoxication, a consequence of the acute systemic hypo-osmolarity caused by drinking excessive amounts of water or administration of hypotonic intravenous fluids. Acute hyponatremia, which can

be induced for example by inappropriate secretion of antidiuretic hormone or renal salt-wasting from secretion of atrial natriuretic hormone, can cause cellular swelling and brain edema. Under these circumstances water moves from extracellular to intracellular sites. Cytotoxic edema may also accompany vasogenic edema in encephalitis, trauma, and stroke.

A family of water channels, the aquaporins, regulate fluid homeostasis in the brain and other organs by facilitating the movement of water through cellular membranes. The 11 known aquaporins (AQP0 to AQP10) consist of two tandem repeats of three transmembrane α -helixes and two connecting loops, each containing an asparagine-proline-alanine motif, that form a membrane pore of 3–6 Å diameter (Figure D–12).

Six family members (AQP1, AQP3, AQP4, AQP5, AQP8, AQP9) exist in the rodent brain. The AQP4 protein is produced by ependymal cells and astrocytes but not neurons. It appears in the endothelial cells and perivascular processes of astrocytes concurrent with the development of the blood–brain barrier; expression is altered in disorders producing blood–brain barrier dysfunction and cerebral edema. The AQP4 and AQP9 channels are found in astrocyte processes in periventricular regions and in the glia limitans bordering the subarachnoid space and thus may have a role in facilitating movement of water between CSF and brain parenchyma. The AQP1 channel appears to transport water at the choroid plexus during CSF formation.

Hydrocephalus Is an Increase in Volume of the Cerebral Ventricles

Hydrocephalus has three possible causes: oversecretion of cerebrospinal fluid, impaired absorption of CSF, or obstruction of CSF pathways. Oversecretion of CSF is rare but is thought to occur in some functioning tumors of the choroid plexus (papilloma) because removal of the tumor may relieve the hydrocephalus. These tumors are associated with subarachnoid hemorrhage and high CSF protein content, which could also impair the absorption of CSF.

Impaired absorption of CSF may result from any condition that raises intracranial pressure, such as thrombosis of cerebral veins or sinuses. Impaired CSF absorption at the arachnoid villi is a common cause of communicating hydrocephalus (enlargement of the entire ventricular system without obstruction of CSF flow) following subarachnoid hemorrhage, trauma, or bacterial meningitis.

Impaired CSF absorption is also believed to be the cause of normal-pressure hydrocephalus, which is characterized by dementia, urinary incontinence, and a disorder of gait called *apraxia*. Brain imaging reveals communicating hydrocephalus, and routine lumbar puncture typically shows normal intracranial pressure. However, continuous intracranial pressure monitoring reveals episodic elevations in intracranial pressure, suggesting that intermittent intracranial hypertension causes the condition. The clinical symptoms are

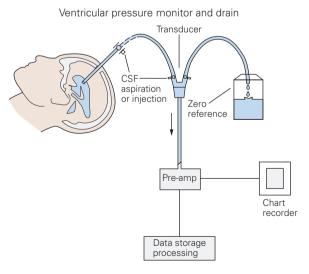

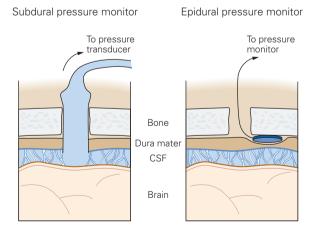

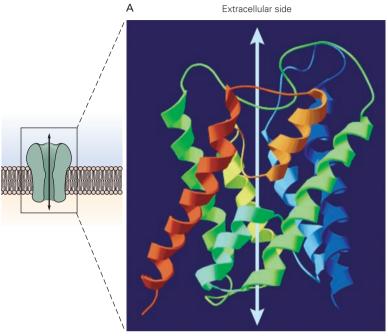

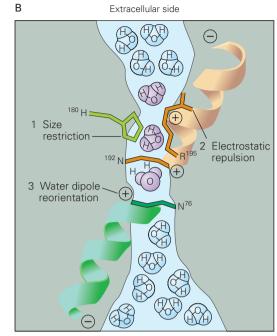

Figure D-11 Techniques for continuous measurement of intracranial pressure. (Adapted, with permission, from Jennett and Teasdale 1981.)

Cytoplasmic side

Cytoplasmic side

Figure D–12 Water transport across cell membranes in the brain is facilitated by membrane-spanning water channels called aquaporins (AQP).

A. Model of a transmembranous AQP1 subunit. The aminoterminus is dark blue and the carboxy terminus is dark orange. Six long membrane-spanning helixes surround two hemipores (loops with short helixes depicted in light blue and light orange) that meet in the center of the lipid membrane bilayer. The arrow indicates the aqueous channel through the protein.

B. Physicochemical features of the AQP1 water channel. Three water molecules (**purple**) represent transient interactions with the pore-lining at discrete sites. Bulk water molecules (**blue**)

occur in the extracellular and intracellular spaces. Three features of the channel make it selective for water. 1. The pore narrows 8 Å above the channel midpoint to a diameter of 2.8 Å. 2. At the narrowest region of the pore conserved residue (Arg-195) forms a barrier to cations, including protonated water (H₃O⁺). 3. Two short helixes meet at the channel midpoint, providing positively charged dipoles that reorient traversing water molecules, disrupting hydrogen bonding in the single-file chain of traversing water molecules and preventing the formation of proton conductance. (Adapted, with permission, from Kozono et al. 2002.)

believed to result from the effects of the expanded lateral ventricles and abnormal absorption of CSF through the ventricular ependymal lining on the surrounding subcortical white matter tracts.

Obstruction of CSF pathways may result from tumors, congenital malformations, or scarring. A particularly vulnerable site for all three mechanisms is the narrow aqueduct of Sylvius. Aqueductal stenosis may result from congenital malformations or gliosis because of intrauterine infection or hemorrhage. Later in life the aqueduct may be occluded by tumor. The outlets of the fourth ventricle may be obstructed by congenital atresia of the foramina of Luschka and Magendie, which may lead to enlargement of all four ventricles (Dandy-Walker syndrome). Obstruction of flow at the basilar cisterns, resulting from conditions such as intraventricular hemorrhage or meningitis, can also cause

enlargement of the entire ventricular system. In early life the cranial vault enlarges with the ventricles; after the sutures fuse, cranial volume is fixed and hydrocephalus develops at the expense of brain volume.

Symmetric Networks Minimize Energy-Like Functions

Hebbian Plasticity May Create Sequential Synaptic Pathways

An Overall View

By ITSELF A SINGLE NEURON is not intelligent. But a vast network of neurons can think, feel, remember, perceive, and generate the many remarkable

phenomena that are collectively known as "the mind." How does intelligence emerge from the interactions between neurons? This is the central question motivating the study of neural networks. In this appendix we provide a brief historical review of the field, introduce some key concepts, and discuss two influential models of neural networks, the perceptron and the cell assembly.

Starting from the 1940s researchers have proposed and studied many brain models in which sophisticated computations are performed by networks of simple neuron-like elements. Most models are based on two shared principles. First, our immediate experience is rooted in ongoing patterns of action potentials in brain cells. Second, our ability to learn from and remember past experiences is based at least partially on long-lasting modifications of synaptic connections. Although these principles are widely accepted by neuroscientists, they immediately suggest many difficult questions.

For example, to our conscious minds, perceiving an object or moving a limb is experienced as a single, unitary event. But in the brain either act is the result of a collection of a stupendous number of neural events—the discharge of action potentials or the release of neurotransmitter vesicles—indiscernible by the conscious mind. How are these events united into a coherent perception or movement?

Storage of our immediate experience in long-term memory is presumed to occur with changes in synaptic connections. But how exactly is a memory divided up and distributed across many synapses? If some synapses are used to store more than one memory, how then is interference between memories avoided? When past experiences are recalled from memory, how

might synaptic connections evoke a pattern of firing that is similar to a pattern that occurred in the past? Finally, when we reason, daydream, or otherwise float in the stream of consciousness, our mental state is not directly tied to any immediate sensory stimulus or motor output. How do networks of neurons dynamically generate the patterns of activity related to such mental states?

These are profound questions. Many hypothetical answers have been proposed in the form of neural network models, a body of work that spans many decades and which we survey here. Although they are far from being tested conclusively, these hypotheses have influenced the research of a number of experimental neuroscientists and are being developed further today by theoretical neuroscientists.

Early Neural Network Modeling

Perhaps the first attempt to explain behavior in terms of synaptic connectivity was Sherrington's reflex arc. A reflex behavior is defined as a rapid, involuntary, and stereotyped response to a specific stimulus (see Chapter 35). For any reflex behavior one can generally identify a reflex arc, a chain of synapses starting from a sensory neuron and ending with a motor neuron. The sequential activation of neurons in this chain is a series of causes and effects that connect the stimulus to the response. The reflex arc can be regarded as an ancestor of neural network models.

In 1938 Rafael Lorente de Nó, a student of Santiago Ramón y Cajal, argued that synaptic loops ("internuncial chains") were the basic circuits of the central nervous system. A synaptic loop is a chain of synapses that starts and ends at the same neuron. It is a closed chain, in contrast to the open chain of a reflex arc. Lorente de Nó suggested that the purpose of these loops was to sustain "reverberating" activity patterns. In fact, Sherrington's student, Graham Brown, in his studies of spinal cord rhythmicity, proposed a related view of the brain, involving intrinsic generation of neural activity rather than stimulus-response relationships. These scientists emphasized that the brain has an intrinsic dynamic richer than that of reflex arcs, which are inactive until stimulated by the outside world.

In an influential book published in 1949, Donald Hebb proposed the idea of a "cell assembly" as a functional unit of the nervous system and discussed the form of synaptic plasticity that would become known as Hebb's rule. (The rule had previously been formulated by several other thinkers, of whom the earliest

was perhaps the philosopher Alexander Bain in 1873.) Hebb argued that repeated synaptic communication between neurons could strengthen the connections between the neurons, creating synaptic loops that were capable of supporting the reverberating activity patterns of Lorente de Nó.

These ideas of Sherrington, Graham Brown, Lorente de Nó, and Hebb were later formalized in mathematical models of neural networks. Two famous classes of models are perceptrons and associative memory networks. *Perceptrons* have been popular as models of the visual system because they illustrate how recognition of an object can be decomposed into many feature detection events. A perceptron can be organized hierarchically, so that the decomposition process begins with simple features at the bottom of the hierarchy and proceeds to complex features at the top, as is thought to occur in the visual system (see Chapter 28).

Associative memory networks have been used to model how the brain stores and recalls long-term memories. Central to these models is Hebb's concept of the cell assembly, a group of excitatory neurons mutually coupled by strong synapses. Memory storage occurs with the creation of a cell assembly by Hebbian synaptic plasticity (see Chapter 66), and memory recall occurs when the neurons in a cell assembly are activated by a stimulus.

The perceptron and the cell assembly have very different synaptic connectivities. As in Sherrington's reflex arc, the polysynaptic pathways in a perceptron all travel in the same overall direction, from the input layer to the output layer. The perceptron generalizes the reflex arc, because it allows many synapses to diverge from a neuron and converge onto a neuron.

The perceptron is a special case of a *feed-forward network*, defined as one with no synaptic loops. As noted above, a synaptic loop is defined as a polysynaptic pathway that starts and ends at the same neuron. Networks with loops are called *recurrent* or *feedback networks*, to distinguish them from feed-forward networks. A cell assembly typically contains loops, and is therefore recurrent.

Lorente de Nó and Hebb postulated that neural activity can persist longer in the brain by circulating through synaptic loops. Thus a cell assembly can maintain a persistent activity pattern resembling patterns observed by neurophysiologists in studies of short-term and working memory. In other words, loops could be important for the generation of persistent mental states in the brain, which are required for behaviors in which stimulus and response are separated by a long

time delay. In contrast, the direct pathways of the perceptron are suited for modeling behavioral responses that immediately follow a stimulus.

Only very simple neural networks are described in this appendix. The "neurons" in these models are much simpler than biological neurons, and the "synapses" do not do justice to the intricacies of biological synapses. When modeling a complex system, simplifying its elements helps one to focus on the properties that emerge from the interactions between them. This strategy has historically been used by neural networks researchers focusing on emergent properties of brain function. More realistic models of how neurons integrate synaptic inputs are described in Appendix F.

Neurons Are Computational Devices

Action potentials and synaptic potentials are dynamic events that involve a complex interplay between the membrane voltage of a neuron and the opening and closing of its ion channels. Computational neuroscientists often ignore these complexities in their thinking and instead rely on the following simplification: A neuron fires an action potential when a sufficiently large number of excitatory synapses onto it are activated simultaneously.

This statement is based on the fact that a single excitatory postsynaptic potential is typically much smaller in amplitude (less than 0.5 mV) than the gap of many millivolts that separate the resting potential from the threshold for an action potential. Therefore, many simultaneous excitatory postsynaptic potentials need to sum in the postsynaptic neuron to drive its voltage over the threshold for firing.

The above simplification of the conditions for neuronal firing has inspired a great deal of mathematical formalism. In 1943 Warren McCulloch and Walter Pitts proposed a model of the computation performed by a neuron and the excitatory synapses converging onto it. The McCulloch-Pitts neuron takes multiple inputs and produces a single output. All inputs and the output are binary variables, 0 or 1. The neuron is characterized by a single parameter θ , its threshold. If a subset of θ or more inputs is equal to 1, then the neuron's output is 1; otherwise the output is 0.

In the biological interpretation of the McCulloch-Pitts model each input variable represents the activation of an excitatory synapse at the neuron. The input is equal to 1 when the excitatory synapse is activated. The parameter θ is used to model the threshold of a biological neuron and is equal to the minimum number of excitatory synapses that must be simultaneously activated to produce

an action potential. In this interpretation the McCulloch-Pitts model formalizes the above caricature of a biological neuron.

Two McCulloch-Pitts neurons can be connected so that the output of one neuron is the input of another. This corresponds to the biological fact that excitatory synapses converging onto a neuron are activated by the discharging of the presynaptic neurons. By making many such connections, it is possible to construct a model of a neural network.

In the McCulloch-Pitts model, neurons are either active ("1") or inactive ("0"). This is admittedly a crude way of describing neural activity, because it does not distinguish between active neurons with different firing rates. But this coarse description is used not only by theorists but also by experimental neurophysiologists, who often speak of active and inactive neurons in the exploratory phases of their experiments before they make precise measurements of firing rates. Although the graded nature of firing rates can be captured using more realistic model neurons (Box E–1), here we will limit ourselves to the McCulloch-Pitts model to minimize the use of mathematical equations.

This simplification also allows the application of ideas from Boolean logic, in which the binary values 0 and 1 correspond to "false" and "true." Boolean logic, named after the British mathematician George Boole, is a formalization of deductive reasoning that is based on manipulations of binary variables that represent truth values. Boolean logic is the mathematical foundation of digital electronic circuits. Using their model, McCulloch and Pitts argued that the activity of each neuron signifies the truth of some logical proposition. They concluded that neurons (and by extension networks of neurons) perform logical computations.

A Neuron Can Compute Conjunctions and Disjunctions

If we accept the idea that biological neurons can perform logical computations, then it is natural to ask what types of computations are possible. We will answer this question by studying the behavior of the McCulloch-Pitts model neuron. Of course, biological neurons are more complex and therefore likely to be more powerful computational devices. But by analyzing the McCulloch-Pitts neuron we can expect to establish lower bounds on the computational power of biological neurons. In other words, if a computation is possible for a McCulloch-Pitts neuron it should be possible for a biological neuron, although the converse is not necessarily true.

Box E-1 Mathematics of Neural Networks

The McCulloch-Pitts neuron is simple enough that its behavior can be described in words. More sophisticated models require the precision of mathematics for a clear formulation.

The linear-threshold (LT) model neuron corrects a shortcoming of the McCulloch-Pitts neuron that all excitatory inputs are equally effective in bringing the neuron to its firing threshold; the number of active inputs is important, but their identities are not. For a biological neuron in which some synapses are stronger than others, such a simplification is not realistic.

To model this aspect of synaptic function, the LT neuron takes the weighted sum of its inputs, where the weights of the sum represent synaptic strengths. If the sum exceeds a threshold, the LT neuron becomes active.

To model a network of LT neurons, assume that their activities at time t are given by the N variables, $x_1(t)$, $x_2(t)$..., $x_N(t)$ which take on the values 0 or 1, that is, a neuron is either active ("1") or silent ("0"). Then the activities at time t+1 are given by

$$x_i(t+1) = H\left(\sum_{j=1}^{N} W_{ij} x_j(t) - \theta_j\right)$$
 (E-1)

where H is the Heaviside step function defined by H(u) = 1 for $u \ge 0$ and H(u) = 0 otherwise, W_{ij} is the strength or weight of the synapse between neuron i and the presynaptic neuron j, and θ_j is the threshold of neuron i. For a network of N neurons, the synaptic weights W_{ij} form an $N \times N$ matrix, and the thresholds θ_j an N-dimensional vector.

The LT and McCulloch-Pitts models are equivalent if the synaptic strengths of the LT model satisfy two conditions. First, the strengths of all excitatory synapses must equal one to yield the uniformity of strengths discussed above. Second, each inhibitory synapse must be so strong that activating it is enough to keep the LT neuron below threshold, no matter how many excitatory inputs are active. This second condition is in accord with the behavior of inhibition in the original McCulloch-Pitts neuron and could be regarded as a crude model of shunting inhibition (see Chapter 10).

The LT neuron of Equation E–1 can perform many different types of computation, depending on the choice of synaptic weights and thresholds. By arguments similar

to those given in the main text, any Boolean function can be realized by combining LT neurons into a network. A perceptron network can be implemented by a synaptic weight matrix in which certain elements are constrained to be zero. (Such elements would give rise to "backwards" pathways in the perceptron model illustrated in Figure E–1.) An associative memory network can be constructed by choosing W_{ij} to be a correlation matrix (see Box E–3).

The LT neuron is either active or inactive, but the firing rates of biological neurons are continuously graded quantities. This can be modeled by replacing the Heaviside step function H in Equation E–1 by some other function F with graded output. Neural activity is described by continuously graded variables $r_1 \dots r_N$ rather than binary variables, which are interpreted as rates of action-potential firing. Furthermore, time can be treated continuously in the differential equation

$$\tau \frac{dr_i}{dt} + r_i = F\left(\sum_{j=1}^N W_{ij} r_j - \theta_j\right)$$
 (E-2)

rather than discretely as in Equation E–1. This type of model is discussed in more detail in Appendix F.

In Equation E–2 the soma of the neuron is regarded as a device that converts input current into the cell's rate of firing. This point of view is often taken by electrophysiologists, who characterize a neuron by its *f-I* curve, plotted by injecting current into a neuron and recording the resulting firing rate. The dendrite of the neuron is assumed to linearly combine the currents produced by its synapses, a good approximation in some biological neurons. Each synapse generates a current that is proportional to the firing rate of its presynaptic neuron.

Equation E–2 is still quite crude in its description of neural activity as an overall firing rate. More sophisticated models have differential equations governing voltages and conductances and generate individual action potentials. For example, the voltages in the numerical simulations of Figure E–5 were generated by leaky integrate-and-fire model neurons. More about this and other spiking model neurons can be found in works listed in the bibliography at the end of the appendix, as well as in Appendix F.

Suppose that the threshold parameter θ of a McCulloch-Pitts neuron is set at a high value, equal to the total number of inputs. Then the neuron is active if, and only if, all of its synaptic inputs are active. In other words, the output of the neuron is the *conjunction* of its input variables, which is also known as the logical AND operation. Alternatively, the threshold can be set at a low value, equal to one, such that activation of one or more synaptic inputs is enough to activate the neuron. In this case the output of the neuron is the *disjunction* of its input variables, which is also known as the logical OR operation.

Although a McCulloch-Pitts neuron can compute some logical functions, it cannot compute others. A famous example is the exclusive-or (XOR) operation. By definition the XOR operation on two inputs results in "1" if, and only if, exactly one of its inputs is "1." Thus if both inputs are "1," the XOR function outputs "0," while the OR function outputs "1." Proving that a single McCulloch-Pitts neuron cannot compute the XOR operation is left as an exercise to the reader. However, XOR can be computed by a network of McCulloch-Pitts neurons, as is explained below.

A Network of Neurons Can Compute Any Boolean Logical Function

What functions can be computed by a network of McCulloch-Pitts neurons? Conjunctions and disjunctions are basic building blocks of Boolean logic. The original definition of a McCulloch-Pitts neuron included both inhibitory and excitatory synapses. It turns out that synaptic inhibition can be used for the operation of negation (logical NOT).

Consider a neuron that is spontaneously active and receives a single strong inhibitory synapse. When the inhibitory synapse is inactive, the neuron is spontaneously active. But when the inhibitory synapse is active, the neuron is inactive, silenced by inhibition. In other words, the neuron responds with 1 when its input is 0 but with 0 when its input is 1. This is exactly the NOT operation.

It is well known that any function of Boolean logic can be synthesized by combining the AND, OR, and NOT operations. Because McCulloch-Pitts neurons can compute all of these operations, it follows that networks of McCulloch-Pitts neurons can compute any function of Boolean logic, including XOR.

Why is it important that these models compute Boolean functions? Boolean logic lies at the heart of modern digital computers. The computers on our desktops, and in fact all digital electronic circuits, are designed to implement Boolean logic. When a digital computer runs a software program, it simply executes sequences of logical operations. Thus networks of McCulloch-Pitts neurons can compute the same functions as digital computers.¹

These facts about networks of McCulloch-Pitts neurons were discovered in the 1940s and 1950s when neural network models played a role in the formal theory of automata and computation. This line of research showed that neural network models have great computational power in principle. Nevertheless, a difficult question remains: How are computations actually performed by brains? This question cannot be answered by formal arguments alone. It is now being addressed both by theoretical and experimental neuroscientists who try to understand how the brain works, and by computer scientists and engineers who create artificial systems that emulate capabilities of the brain.

The notion that a neuron is a device for computing conjunctions and disjunctions is prominent in the ensuing discussion of neural network models of the visual system.

Perceptrons Model Sequential and Parallel Computation in the Visual System

The term *perceptron* was coined in the 1950s by Frank Rosenblatt to describe his neural network models of visual perception. In a perceptron neurons are organized in layers (Figure E–1).² The first layer is the input to the network and the last layer the output. Each layer sends synapses only to the next layer, so that information flows in the "forward" direction from the input to the output. Although perceptrons can be constructed from various kinds of model neurons, we will use the simple McCulloch-Pitts neurons.

The computations in a perceptron, as in the visual system, occur through both sequential and parallel processing of information. The layers of a perceptron can be regarded as a sequence of steps in a computation. The neurons within each layer perform similar operations that are executed in parallel during a single

¹A formal model of a digital computer called a *Turing machine* is more powerful than a network of McCulloch-Pitts neurons because it has a memory with an infinite capacity. But any real digital computer has finite memory and is therefore less powerful than the idealized Turing machine.

²There is some variation in the use of the term "perceptron". Some people call the network in Figure E–1 a "multilayer perceptron," and use "perceptron" to refer only to a network with a single layer of synapses. Here we use perceptron as a generic term covering both multilayer and single-layer perceptrons.

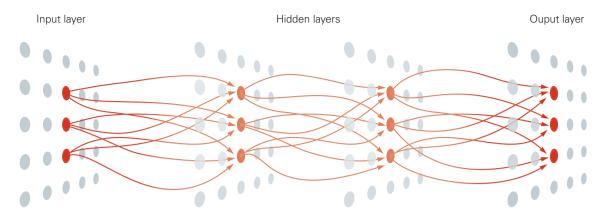

Figure E-1 The perceptron model. A perceptron is a network of idealized neurons arranged in layers with synaptic connections from each layer to the succeeding one. In general, any number of "hidden layers" may intervene between the input

and output. Each disk represents a neuron. An arrow pointing from the presynaptic neuron to the postsynaptic neuron represents a synapse. There are no loops in the network.

step of the computation. Because vision is often quite fast compared to other cognitive tasks, it may require only a few sequential steps, but each step involves a large number of operations performed by many neurons working in parallel. It is natural to represent this kind of computation by a perceptron with a small number of layers, each with many neurons.

Simple and Complex Cells Could Compute Conjunctions and Disjunctions

We shall develop the analogy between perceptrons and the visual system by exploring its implications for primary visual cortex (V1). As discussed in Chapter 27, the "simple cells" of V1 respond selectively to stimuli in the visual field that have a certain spatial orientation. A simple cell responds to a bar of light close to a particular orientation but not to bars with other orientations.

In a classic 1962 paper David Hubel and Torsten Wiesel described this property of orientation selectivity in V1 and also proposed the first model of how it is achieved. They assumed that what they called a "simple" cortical cell receives synaptic inputs from cells in the lateral geniculate nucleus (LGN) and suggested that orientation selectivity of the simple cell in V1 depends on the spatial arrangement of the receptive fields of the LGN cells. Thus, if the center-surround receptive fields of the LGN cells were arranged along a straight line (see Figure 27–3), a bar of light with the same orientation as this line would activate all the LGN inputs of the simple cell simultaneously, driving the

cortical simple cell that receives these inputs above the threshold for firing action potentials. Conversely, a bar of light at nonpreferred orientations would stimulate only some of the LGN inputs, leaving that simple cell below threshold for firing.

The preceding model of a simple cell can be interpreted as a McCulloch-Pitts neuron computing an AND operation (Figure E–2A) because a simple cell fires when *all* of its LGN inputs are activated. Recall that a McCulloch-Pitts neuron computes a conjunction if its threshold is set sufficiently high, and intuitively it makes sense that a high threshold goes along with high selectivity.

In addition to simple cells, V1 also contains "complex" cells, also first described by Hubel and Wiesel. Like simple cells, complex cells are orientation selective, but their responses are not sensitive to the location of the stimulus within the receptive field, whereas simple cells are quite sensitive to the precise alignment of the stimulus within the excitatory subregions of their receptive field.

Hubel and Wiesel proposed that a complex cell receives synaptic input from simple cells with similar orientation selectivity (Figure E–2C). The receptive fields of the simple cells add together to form the receptive field of the complex cell. If a visual stimulus with the preferred orientation activates any one of the simple cells, the complex cell is driven over the threshold for firing. This model is intended to explain why spatial location of the stimulus in the receptive field is not a factor in activating the complex cell.

This model of a complex cell can be interpreted as a McCulloch-Pitts neuron computing an OR operation (Figure E–2B) since a complex cell fires when *any*

of its simple cell inputs is activated. A McCulloch-Pitts neuron computes a disjunction if its threshold is set sufficiently low, and it makes sense that a low threshold is appropriate for nonselective responses.

In effect, Hubel and Wiesel imagined simple and complex cells as McCulloch-Pitts neurons, although they did not use such language. For a McCulloch-Pitts neuron the threshold determines whether responses are selective or invariant. The simple cell's high threshold is responsible for the cell's orientation selectivity, while the complex cell's low threshold accounts for the

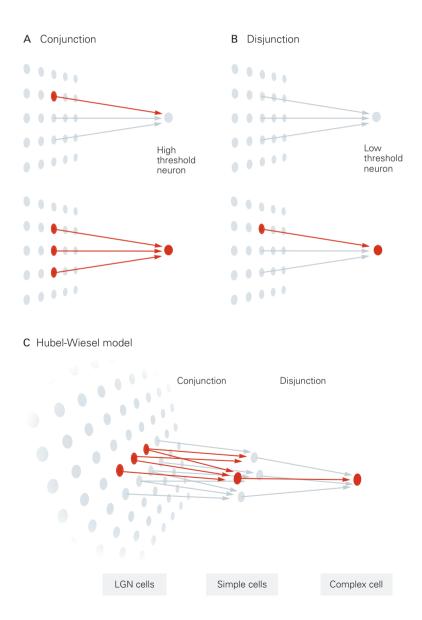

invariance of its response to the location of the stimulus within its receptive field.

The Primary Visual Cortex Has Been Modeled As a Multilayer Perceptron

If the Hubel-Wiesel model is extended to many neurons, each with a receptive field that covers a different location in the visual field and tuned to a preferred orientation, then it amounts to a perceptron with three layers of neurons (Figure E–3).

Figure E-2 A perceptron implementing conjunction (AND), disjunction (OR), and the Hubel-Wiesel neurobiological model of simple and complex cells in visual cortex. Neurons are represented by disks and synapses by arrows. Active neurons and synapses are colored red.

- A. A neuron with a high threshold can compute the conjunction of three inputs. The neuron does not respond to only one input (top) or two inputs (not shown). It becomes active only when all three inputs are active (bottom).
- B. A neuron with a low threshold can compute a disjunction of three inputs. The neuron remains inactive if all of its inputs are inactive (top). It becomes active if a single input neuron is active (bottom) or more than one input neuron is active (not shown).
- C. In this realization of the Hubel-Wiesel model a disjunction neuron (right) receives inputs from a set of conjunction neurons (middle), which in turn receive inputs from a grid of neurons (left). The neurons in the grid represent lateral geniculate nucleus (LGN) cells, which are assumed to be either all ON-center or OFF-center cells and retinotopically organized so that the location of each cell in the grid corresponds to the location of its receptive field on the retina. A horizontally oriented visual stimulus activates three LGN cells in a row, which activate a "simple cell" (conjunction) that in turn activates a "complex cell" (disjunction). Like actual simple cells of primary visual cortex, each conjunction neuron responds selectively to stimuli with a particular orientation (horizontal in this case) and at a particular location. Likewise, like actual complex cells, the disjunction neuron responds selectively to stimuli with a particular orientation but is invariant to the exact location of the stimulus.

Indeed, like this perceptron, visual areas of the brain generally have a retinotopic organization: Neighboring cells have receptive fields that cover adjacent areas in the visual field. This means that a sheet of cortical tissue functions like a map of the visual field, and patterns of activity can actually resemble images. Similarly, each layer of the model in Figure E–3 is retinotopically organized so that at any moment a map of the overall activity pattern of its neurons depicts the stimulus image. Connections between the layers respect the spatial arrangements of receptive fields described above and shown in Figure E–2. The thresholds are set to yield conjunctions and disjunctions in simple cell and complex cell layers, respectively.

The structure of the model is idealized in a number of ways to facilitate understanding. All cells are arranged in uniformly spaced grids. Furthermore, the simple cell and complex cell layers each have a number of "feature maps." Each cell in a feature map detects exactly the same feature but in a different location of the visual field (Figure E–3). In the cortex the cells detecting different features would be intermingled, but in the model they are segregated for convenience.

A map of active neurons in the LGN layer of the model accurately represents the visual stimulus, whereas the simple and complex cell layers contain more abstract representations of the stimulus because of the orientation selectivity of neurons. In particular, the representation of the stimulus in the complex cell layer is robust and does not reflect small variations in the stimulus (see Figure E–3).

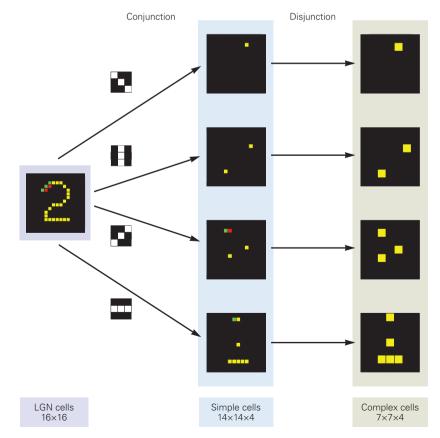

Selectivity and Invariance Must Be Explained by Any Model of Vision

The dichotomy between selectivity and invariance has been important in our discussion of the primary visual cortex and simple stimuli like bars. More generally, this dichotomy is relevant throughout the visual system and even for complex stimuli like entire objects. Let's step back and think about the computations that the entire visual system must accomplish.

Even though the act of seeing appears effortless for humans and animals, vision is a difficult computational problem. In spite of enormous progress in

Figure E-3 A perceptron implementing the Hubel-Wiesel model of selectivity and invariance. The network in Figure E-2C can be extended to grids of many cells by specifying synaptic connectivity at all locations in the visual field. The resulting network can be repeated four times, one for each preferred orientation (horizontal, vertical, and two diagonals). This yields four retinotopically organized grids of simple cells, one for each preferred orientation, as well as four grids of complex cells. Each grid is called a feature map. Throughout the network the responses to two slightly different images of the numeral 2 are superimposed for comparison. A vellow pixel indicates a neuron that responds to both stimuli. A red pixel indicates a neuron that responds to one of the stimuli, and a green pixel indicates a neuron that responds to the other.

In the LGN layer the difference between the two stimuli is evident (see red and green pixels at the top of the numeral). In the simple cell layer the bottom two feature maps show different responses to the images (red and green pixels), but the top two are the same (all yellow pixels). Finally, the responses of the complex cells are the same for both images (all yellow pixels). Thus invariance and selectivity occur together in one network, although the invariance is limited (it does not hold for all distortions) and the selectivity is fairly simple.

algorithms, speed, and memory capacity, modern digital computers are still far from equaling the performance of biological vision systems. In particular, one of the main functions of vision is the recognition of objects. One reason this task is difficult for computers is that the images of a single object are highly variable. Factors such as lighting, location, and distance all cause changes in retinal images that the visual system must ignore in order to recognize an object—recognition requires some invariance in responding. However, the visual system cannot ignore all changes because it has to distinguish between different objects—it must therefore also be selective for certain aspects of images. Although the properties of invariance and selectivity may seem conflicting, they are somehow reconciled by the visual system.

How does the visual system accomplish object recognition? Neurophysiologists have investigated this question by recording from high-level visual areas, such as inferotemporal cortex. To give one example of their findings, certain inferotemporal neurons respond selectively to images of faces. These face-selective neurons have large receptive fields and the exact location of the face within the receptive field is not a factor in the cells' responses. Instead, the responses appear to be closely related to complex features or entire objects rather than simple features like bars or edges.

How are selectivity and invariance achieved by the face-selective neurons? According to one theory, all visual areas of cortex are arranged in a hierarchy (see Figure 28–2) and the Hubel-Wiesel model of simple and complex cells in the primary visual cortex (V1) can be generalized to the higher levels of the visual system. In this hierarchical model V1 is at the bottom and areas in the inferotemporal cortex are near the top. Neurons near the bottom of the hierarchy are selective for simple features, have small receptive fields, and are sensitive to small changes in stimulus location. Neurons near the top of the hierarchy are selective for complex features, have large receptive fields, and are invariant to large changes in stimulus location. Neuronal connections from each level to the next are organized so as to carry out computations analogous to the ones performed by simple and complex cells in V1. As we shall see, this hierarchical conception of visual recognition of objects has been formulated precisely in a number of neural network models.

Visual Object Recognition Could Be Accomplished by Iteration of Conjunctions and Disjunctions

Could perceptrons be used to model not just V1 but also the rest of the visual system? We introduced the

idea that conjunctions create selectivity in V1 and disjunctions create invariance. Repeated alternation between conjunctions and disjunctions can be used to build up progressively greater selectivity and invariance, culminating in invariant recognition of entire objects.

Indeed, this idea was implemented in 1980 by Kunihiko Fukushima in the *Neocognitron*, a network model designed to recognize handwritten digits. Handwritten numbers may be less complex than images of natural stimuli such as faces or animals, but they are still quite challenging to recognize, as postal workers or anyone who has ever graded handwritten exams can attest. Indeed, digits produced by different writers often look very different, and even repetitions by a single writer can vary considerably.

The Neocognitron has a multilayer, feedforward architecture like that of a perceptron (although inhibition is treated somewhat differently).3 The first layer functions like a retina in which neurons represent an image of a handwritten digit, and subsequent layers contain multiple feature maps (Figure E–4). Although the first layers are analogous to the layers of simple cells and complex cells of the network in Figure E-3, the subsequent layers are meant to model visual areas of cortex beyond V1. Using Boolean logic as an approximation of the operations performed by the elements in the Neocognitron, one can say that layers alternate between computing conjunctions and disjunctions.⁴ In other words, the conjunction-disjunction scheme of the Hubel-Wiesel model is cascaded to form a hierarchical system. In the output layer retinotopic organization disappears completely. There are only 10 output neurons, each of which is selective for one of the digits "0" through "9." In a number of simulations the output neurons show an impressive degree of invariance to the location of the digit in the retina as well as to distortions of the digit.

A similar model was later developed by Yann LeCun and his colleagues. This model, called *LeNet*, adheres closely to the standard definition of a perceptron. The backpropagation algorithm was used to change the synaptic strengths of LeNet so as to reduce the error rate in recognizing images (Box E–2). LeNet achieved sufficient accuracy in recognizing handwritten characters to be used in some commercial applications.

³The strengths of the synapses in the Neocognitron were not specified by its designer. Instead, the Neocognitron learned from a sequence of visual stimuli through synaptic modifications based on a model of Hebbian plasticity (see Box E–2).

⁴Boolean logic is just an approximation, as the model neurons in the Neocognitron are actually analog rather than binary.

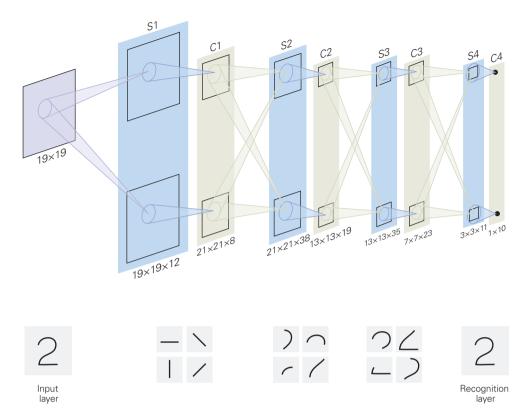

Figure E-4 The Neocognitron model of digit recognition. Each layer in the network is composed of a set of feature maps, and alternating layers contain "S-cells" or "C-cells." All feature maps are retinotopically organized because each cell receives input from neighboring cells of the previous layer. Each cell in a feature map detects the same feature but at different locations in the image.

An S-cell is analogous to a simple cell in the Hubel-Wiesel neurobiological model. It detects conjunction of features detected by C-cells in the previous layer. A C-cell is analogous to a complex cell in the Hubel-Wiesel model. It can be activated by any of the S-cells in the previous layer, which detect the same feature but at slightly different locations in the image.

Receptive fields of cells become larger until the retinotopic organization vanishes completely in the final (recognition) layer.

The Neocognitron was constructed for the purpose of recognizing images of handwritten digits. Accordingly, the output neurons are detectors for the digits "0" through "9" and are highly invariant to small variations. Each S-cell layer generates more complex feature selectivity, and each C-cell layer yields more spatial invariance.

The images at the bottom are examples of preferred stimuli of cells in each layer. S1 and C1 cells respond selectively to oriented bars; S2 and C2 cells are selective for more complex features, such as the conjunction of bars; S3 and C3 cells are selective for still more complex features.

Its descendants are still being used today in the field of computer vision and are competitive with other stateof-the-art approaches.

In the Neocognitron and LeNet the Hubel-Wiesel neurobiological model of V1 is elaborated to the entire process of object recognition. In spite of several decades of intense scrutiny, there remain significant hurdles to testing neural network models of visual processing. To test a model two questions must be addressed. Are there synaptic connections in the brain like those of the model? Is the model a good approximation without other types of connections that are not included? Much experimental evidence concerning

these questions is rather indirect and circumstantial. In particular, anatomical techniques for determining the connectivity of cortical circuits are still in their infancy. For example, there is no direct anatomical evidence for the hypothesis that simple cells in V1 are driven by LGN neurons with receptive fields lined up in a row, as originally proposed by Hubel and Wiesel, although there is some indirect physiological evidence.

As mentioned earlier, attempts have been made to arrange visual areas of cortex in a hierarchy that is consistent with the known anatomical connections between areas. When the visual system is modeled as a perceptron, only "bottom-up" connections are included. In

Box E-2 Learning in Neural Networks

The brain can perform many computational tasks that are beyond the capabilities of today's electronic computers, but it is also remarkable for another reason: It is a self-assembled system, wiring up its own synaptic connections, unlike an electronic computer that is actually built by external agents (humans or machines).

To emulate this process of self-assembly or self-organization, many neural models are equipped with dynamic processes that continually reorganize their synaptic connections. Some processes create or eliminate neurons or their connections, whereas others adjust the strengths of existing synaptic connections or change other properties of neurons.

To describe the process of self-organization, it is helpful to introduce some terminology for describing the synaptic organization of neural networks. The term *synaptic weight* is often used to refer to the strength of a particular synaptic connection, whereas the term *synaptic weight matrix* applies to the set of all synaptic weights in a network. The strength of the synapse onto neuron i from neuron j is written as W_{ij} . This is the element of the weight matrix located at the intersection of row i and column j (see Box E–1).

In many neural network models the weight matrix evolves in time according to a *synaptic plasticity rule*, a mathematical model governing the modifications of synaptic strengths. This is often called a *learning rule*, although strictly speaking, learning is a behavior of a network rather than a synapse.

The network typically starts out in a naïve state, that is, the weight matrix is initialized with random values. Then the network is exposed to a series of stimuli, each of which causes the weight matrix to be modified by the learning rule. Learning rules can take many forms. Much effort has been devoted to devising them and exploring their properties. The Hebbian rule is popular in neurobiological models; with this rule synapses are modified based on temporally contiguous activity of presynaptic and postsynaptic neurons.

It is common to apply the same learning rule to all synapses (or sometimes all excitatory synapses). In spite of this uniformity, the weight matrix becomes heterogeneous because the learning rule depends on activity, and activity patterns are typically nonuniform across a network. Therefore, very complex networks can be produced by a simple learning rule.

In some cases the life of the network is separated into training and operating phases. In the training phase synapses change, whereas in the operating phase the learning rules are turned off. This is analogous to natural development in which plasticity seems particularly strong in juvenile animals. In other cases the learning rules may be turned off gradually. In fully online learning the learning

rules are never turned off, so that the network is always able to adapt to new situations.

It is commonly assumed that reorganization of neural networks in the brain is a decentralized process in which synapses are modified as a result of the interaction of the pre- and postsynaptic neurons rather than in response to signals from some central authority. The Hebbian rule is an example. A consequence of such localized self-organization is that one synapse on a neuron can be modified while another remains unchanged. Such specificity is generally observed in biological experiments on Hebbian plasticity, although some exceptions have been reported.

In addition to signaling in the pre- to postsynaptic direction, retrograde messengers such as nitric oxide may also play a role in synaptic plasticity (see Chapter 11), although their role has not been extensively explored in models. The diffuse neuromodulatory systems also have effects on synaptic plasticity (see Chapter 13), and some neural network models have attempted to include interaction between global signals from a central source and local signals as a factor in synaptic modification.

Learning rules are sometimes classified as unsupervised or supervised. *Supervised learning* involves an external "teacher" that evaluates the performance of the entire network and sends a reward or error signal that somehow reaches the synapses. The learning rule is devised so that it produces synaptic modifications that improve the performance of the network as evaluated by the teacher.

One of the most popular supervised learning methods is known as *backpropagation*. When implemented in a perceptron an error signal is propagated back through the network, starting with the output neurons and moving toward the input neurons. The synapses are then modified based on neural activity and the backpropagated error signal.

Backpropagation has been used by engineers for practical applications, such as a computer system for recognizing handwritten numbers based on LeNet. However, it is unclear whether backpropagation is a biologically plausible learning mechanism, even if it may be useful for engineers.

Using *Unsupervised learning* rules, such as the Hebbian rule, the network learns from sensory inputs without an explicit error signal. These learning rules can have a number of computational functions, such as associative learning, discovering useful stimulus features, or reducing the dimensionality of complex stimuli. They have been used to model the self-organization of feature maps in the primary visual cortex during the course of neural development (see Box E–3), as well as to train networks like the Neocognitron.

reality, however, there are also "top-down" connections. In some cases, such as the pathways between LGN and V1, the top-down connections far outnumber the bottom-up ones. It is thought that top-down connections are important for allowing cognitive factors such as expectation to influence perception.

Given these uncertainties and limitations, how useful are perceptrons as models of vision? Although, perceptrons are simplistic—they encompass only a subset of the connections in the visual system—they may capture some essence of the way that neural circuits perform visual computations. Indeed, perceptrons perform impressively on visual tasks such as recognizing handwritten digits, although they still fall short of human performance. Such engineering applications show how far one can push the simple ideas embodied in the perceptron.

Neural networks like the Neocognitron and LeNet model the visual system as a perceptron organized into a hierarchy of feature detectors. These models propose an answer to one of the questions posed at the beginning of this appendix: How is the psychological event of recognizing an object related to the huge number of neural events that underlie it? In a hierarchical perceptron the recognition of an object involves a relatively small number of sequential steps, each of which consists of a large number of operations executed in parallel. Each operation is very simple, carried out by a neuron that is activated when its synaptic inputs drive it above threshold. The sequential steps alternate between selectivity for more complex features and invariance to small distortions of these features. The neurons at the end of this sequence are selective for entire objects, ignoring variations in their appearance. Thus object recognition can be considered as an emergent property of the network, one that requires the coordinated activation of many neurons, located at many different steps.

Fifty years after Rosenblatt's pioneering work it is clear that perceptrons have been important in developing models of computations in the visual system. In the study of visual perception, as in other fields of science, formal models have proved to be valuable aids to experimentalists.

Associative Memory Networks Use Hebbian Plasticity to Store and Recall Neural Activity Patterns

The sight of a familiar face evokes a name. A simple odor triggers the vivid recollection of a past meal and the persons who were there. These everyday experiences

illustrate that the facts and ideas stored in our memories are associated with each other. Philosophers and psychologists have argued that association is the basic principle of all mental activity. Neuroanatomists have studied the way that neurons are bound together in a web of synaptic connections. The two traditions converge in an intuitively appealing idea: Perhaps synaptic connections are the material substrate of mental associations.

This idea has been formalized in a number of neural network models of associative memory. A fundamental assumption in these models is that information is transferred back and forth between neural activity and synaptic connections. When novel information first enters the brain it is encoded in a pattern of neural activity. If this information is stored as memory, the neural activity leaves a trace in the brain in the form of modified synaptic connections. The stored information can be recalled when the modified connections again become active. This scheme assumes that synaptic connections remain stable for long periods of time, whereas neural activity is ephemeral and represents immediate experience only.

The transfer of information from neural activity to synapses is hypothesized to occur through Hebbian synaptic plasticity: A long-lasting increase in synaptic efficacy is induced if the presynaptic neuron repeatedly participates in the firing of its postsynaptic neuron (Box E–3). Some prominent forms of long-term potentiation involving the NMDA-type glutamate receptor are regarded as Hebbian (see Chapter 67). Conversely, the transfer of information from synapses to neural activity is thought to occur through a process of pattern completion in which activity spreads through an assembly of neurons coupled by synaptic loops. This idea is explained in more detail below.

Hebbian Plasticity May Store Activity Patterns by Creating Cell Assemblies

How might Hebbian plasticity transfer information from neural activity into the synapses of a neural network? One scenario is illustrated in Figure E–5, which depicts a population of excitatory neurons that could represent pyramidal neurons in the hippocampus or neocortex. It is common to assume that Hebbian plasticity modifies the synapses between pyramidal neurons but does not modify synapses involving inhibitory neurons. According to this theory, inhibitory neurons play only a supporting role in memory storage and recall by helping to prevent overexcitation of the network, or "confused" recall of multiple memories

Box E-3 Mathematical Models of Hebbian Plasticity

Associative memory networks were developed by a number of researchers.¹ In their modern form they have two essential features. First, the synaptic strengths are specified by a special type of matrix, called a correlation matrix. Second, the neurons are nonlinear, which enhances the ability of the models to perform the operation of pattern completion described in the main text.²

To store an activity pattern in long-term memory in a nonlinear network of the form written in Equation E–1 in Box E–1, synaptic strengths are changed by the *Hebbian rule*:

$$\Delta W_{ij} \propto x_i x_j$$
 (E-3)

This synaptic learning rule is Hebbian because it depends on the simultaneous activation of the postsynaptic neuron i and the presynaptic neuron j. (For binary neurons the change in Equation E–3 is only nonzero if x_i and x_j are both equal to 1.) If Equation E–3 is repeatedly applied with activity patterns drawn from an ensemble, then W_{ij} becomes proportional to the statistical *correlation* between the activities of neurons i and j (hence the term *correlation matrix*).

A popular modification of the basic Hebbian rule is to replace Equation E–3 by the *Covariance rule*:

$$\Delta W_{ii} \propto (x_i - \langle x_i \rangle)(x_i - \langle x_i \rangle) \tag{E-4}$$

where $\langle x_i \rangle$ is the average activity of neuron *i*. When this is applied to an ensemble of activity patterns, W_{ij} becomes proportional to the statistical *covariance* between the activities of neurons *i* and *j*.

The number of patterns that can be stored in synaptic connections is limited because the patterns eventually interfere with each other (see Figure E–6). The maximal number that can be stored is called the *capacity* of the network. In 1985 Daniel Amit, Hanoch Gutfreund, and Haim Sompolinsky introduced techniques from the statistical physics of disordered systems to calculate memory capacity. Later researchers used these techniques to find that the covariance rule of Equation E–4 is generally superior to the basic Hebbian rule of Equation E–3 because it reduces interference between patterns and therefore enhances storage capacity.

Physiologists have found that Hebbian plasticity can depend on the precise timing of presynaptic and postsynaptic spiking. One example of such a mechanism is spike timing-dependent plasticity (see Chapter 67). To incorporate this dependence, models more sophisticated than Equations E–3 and E–4 have been proposed (see the bibliography at the end of the appendix).

The main text of this appendix focuses on the use of the Hebbian rule in models of associative memory. However, the Hebbian rule has also been used to model the development of retinotopic maps in visual areas of cortex. Also, it is believed that Hebbian plasticity allows neuronal activity to influence the patterning and refinement of connections during neural development (see Chapter 56). In 1973 Christoph von der Malsburg advanced a neural network model of primary visual cortex in which Hebbian plasticity underlies the self-organization of orientation maps when the model network is exposed to visual stimuli.

In 1982 Teuvo Kohonen proposed a simplification of von der Malsburg's model, known as the self-organizing map (SOM). Kohonen showed how the SOM served as a general method of mapping the abstract high-dimensional space of stimuli onto a low-dimensional neural representation, as in a sheet of cortical tissue. Kohonen's learning rule causes neighboring neurons in the network to develop preferences for similar stimuli. This yields a low-dimensional map of the stimulus space based on similarities between sensory inputs.

at the same time. For simplicity, inhibitory neurons are not included in the model in Figure E–5.

The initial state of this network has no connections between neurons (Figure E–5A). This should not be taken literally. It depicts an initial situation in which synapses exist but are all very weak. Now suppose that three neurons are stimulated by synapses from sources

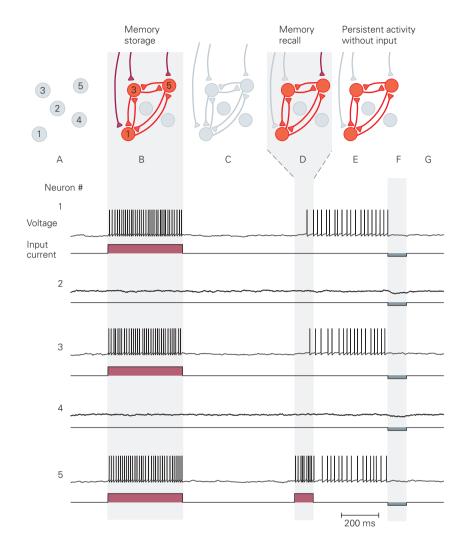

outside the circuit (Figure E–5B). This situation corresponds roughly to activation of a distributed pattern of neural activity in the brain by a sensory stimulus, as is often observed in neurophysiological studies. Every synapse between a pair of active neurons is therefore exposed to coincident presynaptic and postsynaptic activity, thus strengthening the synapses.

¹See J.A. Anderson and E. Rosenfeld, *Neurocomputing: Foundations of Research*, 1988, IT Press.

²These two properties were first combined in associative memory networks by Shun-ichi Amari and Kaoru Nakano working independently in 1972.

Figure E-5 Associative memory and persistent activity in a network of model neurons. Numerical simulations were done using the leaky integrate-and-fire model neuron described in Appendix F. This model neuron generates spike times but not the detailed shape of the action potential.

- A. The synaptic connections between five neurons are initially very weak or nonexistent, and here are not drawn at all. Neurons 1, 3, and 5 are about to be activated by external input.
- B. Input current activates the three neurons and Hebbian plasticity causes the synaptic connections between the neurons to strengthen, a form of associative memory storage.
- C. When the input current ceases neuronal activity also ceases. The Hebbian strengthening of connections occurs during this interval after some time delay.
- D. Input current stimulates just one of the original three neurons, but the excitatory connections complete the entire pattern. All three neurons of the pattern become activated
- E. Even after the input current has ended, the neurons remain persistently active.
- **F.** A nonselective inhibitory input to all the neurons (circuit not depicted) quenches the persistent activity pattern.
- G. The circuit returns to a quiescent state.

After this strengthening has occurred, a group of three neurons that are strongly coupled by excitatory synapses form a *cell assembly* (Figure E–5C). Neuroscientists generally use this term rather imprecisely. One must look to mathematical models of networks for more precise definitions, which generally have something to do with the presence of strong mutual excitatory interactions within a group of neurons. The word "assembly" emphasizes that the group did not initially exist but was constructed through the strengthening of the synapses of the neurons in the group, which in turn was caused by the simultaneous activation of the neurons.

In effect, the information in the original activity pattern is transferred to the pattern of strong synapses in the cell assembly. If the synaptic changes persist, the information is maintained even after the original activity pattern has ceased. It could be said that the network has learned an activity pattern by storing it into its synaptic strengths. Because of this, the cell assembly can replicate the original activity pattern, as will be explained below.

Cell Assemblies Can Complete Activity Patterns

If inputs are limited to one neuron in the three-cell assembly, the neuron starts to generate action potentials (Figure E–5D). Although the external inputs to the other two neurons do not change, they also become activated after a short latency because they are driven by synaptic input from the first neuron. This spreading of activation from one neuron to the other two is an example of *pattern completion*. Researchers have scaled up the same idea to very large networks.

Such a neural process is thought to be responsible for the psychological phenomenon of memory

retrieval. Consider the example of seeing a friend and remembering his name and occupation. Partial information triggers recall of more information based on the completion of a neural activity pattern.

In the simulation in Figure E–5, stimulating any one out of the three neurons would result in completion of the entire pattern. This is a kind of symmetry and is analogous to the way in which memory retrieval can be symmetric; it is equally possible for a face to evoke recall of a name and vice versa. Symmetric pattern completion is possible for a cell assembly because of the lack of directionality in its connectivity. Activity can spread in any direction within a cell assembly except that activity in the last layer cannot spread backward to the rest of the network.

In the CA3 region of the hippocampus, a brain area that has been implicated in episodic memory (see Chapter 65), pyramidal neurons make synapses onto each other in a recurrent fashion, and Hebbian plasticity has been observed at these synapses. Therefore CA3 seems a prime candidate for a network containing cell assemblies, as many theorists have speculated in the past. The hypothesis that Hebbian synaptic plasticity stores memories as cell assemblies in CA3 has been investigated in studies of hippocampal place cells in rodents, the connections between which are thought to store spatial memories (see Chapter 67). Susumu Tonegawa and his colleagues created mutant mice in which a subunit of the NMDA-type glutamate receptor was deleted from CA3 pyramidal neurons. Long-term potentiation was impaired at these synapses, supporting the idea that the NMDA receptor is critical for Hebbian synaptic plasticity. Interestingly, mutant mice are still able to form spatial memories but have difficulty recalling them if some of the original visual landmarks are missing. Tonegawa and his colleagues interpreted this deficit in recall as impaired pattern completion, and ascribed it to impaired formation of cell assemblies in CA3.

Cell Assemblies Can Maintain Persistent Activity Patterns

Up to now our discussion of memory storage in synaptic connections has focused on long-term memory. Recall of a long-term memory occurs through the reactivation of a previous activity pattern, triggered by activation of a subset of the pattern. Once the activity pattern has been reactivated it can persist even after the extrinsic drive has ended because the neurons excite each other through their mutual excitatory connections.

Such persistent activity could also function as a short-term memory trace of the input that activated it.

Short-term memory is generally regarded as distinct from long-term memory. For example, the famous patient H.M. lost the ability to store new long-term memories but had intact short-term memory, evidence that these are two distinct functions (see Chapter 65).

A classic example of short-term memory is the temporary memorization of a phone number for a few seconds after reading or hearing it. After dialing the phone number the information is rapidly lost from memory. If the phone number becomes too long, as when dialing internationally, it can be difficult to retain for even a few seconds. As this example illustrates, short-term memories last for only a very short time and contain limited information. In contrast, long-term memories can last a lifetime, and our brains seem to have virtually unlimited capacity for them.

As described in Chapter 67, similar short-term persistent activity has been observed in the primate brain during the performance of delayed-match-to-sample tasks that are designed to test short-term memory. For example, in each trial of an experiment a monkey views a sample image on a screen, then a blank screen during a delay period, and then another image. The monkey is trained to indicate whether the second image matches the first. In the primary visual cortex neural activity is observed only when the images are presented. However, in higher-level areas, such as inferotemporal and prefrontal cortex, persistent activity is also observed during the interval between images (see Figure 28–11). By sampling many neurons during this delay period, neurophysiologists have recorded distinct activity patterns corresponding to different sample images, suggesting that these activity patterns encode information about previously viewed images.

To summarize, the cell assembly concept has been used to explain both long-term and short-term memory. According to this concept a long-term memory is stored as strengthened connections between neurons in a cell assembly, while a short-term memory is maintained by persistent activity of the neurons in a cell assembly. Whether these ideas are correct remains uncertain, and some of their problematic aspects will be noted later. It should also be noted that not all associative memory networks depend on persistent activity. For example, in the network in Figure E–5 some numerical parameters could be changed so that pattern completion occurs during the stimulus presentation but not after the stimulus is gone.

Interference Between Memories Limits Capacity

Figure E–5 illustrates the storage and retrieval of a single activity pattern. In fact, however, a single network

can store multiple patterns. If Hebbian synaptic modifications store multiple patterns, many cell assemblies are created. A stored pattern can be retrieved by stimulating some of the neurons in the corresponding cell assembly, leading to completion of the entire activity pattern.

However, the storage capacity of a network is not infinite. If the cell assemblies are completely nonoverlapping (share no neurons in common) they will not interfere with each other (Figure E–6A), and in these cases the number of patterns that can be stored is equal to the total number of neurons in the network divided by the size of a cell assembly.

Higher storage capacity can be achieved if the cell assemblies overlap (share neurons). However, overlap means there is the possibility of interference (Figure E–6B). Interference can lead to corruption of memories, so that the activity patterns expressed by the network deviate from the original patterns that were stored by Hebbian plasticity. If we attempt to store too many patterns in the network, interference eventually becomes catastrophic—the stored patterns disappear altogether. Therefore interference effects limit the storage capacity

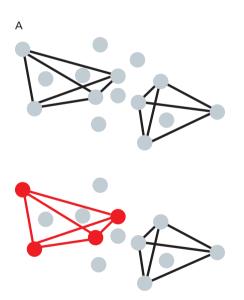

of the network, and mathematical theorists have studied these effects in detail.

Synaptic Loops Can Lead to Multiple Stable States

To describe how cell assembly can maintain different types of activity patterns, we use the concept of *multi-stability*, a term from dynamical systems theory.

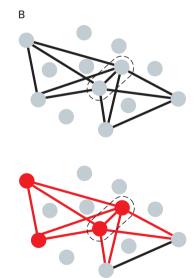

In Figure E–5 the circuit is active during interval E but quiescent during interval G. During the quiescent and active states there is no external input, yet the circuit has two very different firing patterns. Thus the network possesses two possible stable states (active and inactive) for a single input, a phenomenon known as *bistability*. The transient currents at interval F in Figure E–5 switch the circuit from one stable state to the other.

A network with multiple cell assemblies is said to be *multistable* because activation of any one cell assembly produces a distinct stable state of the network. When a multistable system is at a steady state, this state depends on past as well as present input. This dependence on the past explains why the transient inputs of Figure E–5 can have a lasting effect on activity.

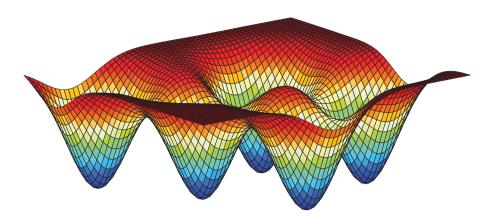

A. Two nonoverlapping cell assemblies. Each assembly is a group of neurons that is fully coupled by strong excitatory synapses. Because the cell assemblies share neither neurons nor synapses in common, they are completely independent. One cell assembly alone can be activated (red) or both assemblies can be activated simultaneously (not shown).

B. Two overlapping cell assemblies. Because some neurons are involved in both cell assemblies (dashed line), there is potential for interference. Activation of one cell assembly could potentially spread to the other cell assembly (lower drawing). This can be prevented. If the threshold for neural activation is sufficiently high, the neurons belonging uniquely to the second cell assembly remain below threshold. Conversely, if the threshold is low, then it will be impossible to activate a single cell assembly without the other (not shown).

Figure E-7 Multiple stable states can be depicted as minima of an energy-like function. The dynamics of a multistable dynamical system can be visualized as descent on an energy landscape with multiple valleys. In a neural network model, this landscape would represent the space of all potential activity patterns and the valleys, or "attractors" (ie, the patterns that are stable and "attract" the activity). Such attractors could represent memories or, more generally, solutions to a computational problem.

Multistability is caused by the connectivity of the cell assemblies. More generally, networks that contain synaptic loops (a cell assembly is a special case of this) can have multiple stable states. In contrast, a perceptron is a type of network that has no loops and does not exhibit multistability. A network with multiple stable states is often called an *attractor neural network*, borrowing a term from dynamical systems theory. A stable steady state is called an attractor of the dynamics because dynamical trajectories (the temporal evolution of the activity of the network) that start from similar initial conditions will converge (are attracted) to the stable state.

Symmetric Networks Minimize Energy-Like Functions

Further insight into multistability can be gained from a physical analogy. If the curved surface shown in Figure E–7 is slippery, a small object placed on the surface will slide downhill, ultimately coming to rest near the bottom of a valley, assuming that there is a little friction to damp the motion. The object could end up in any one of the valleys, depending on its starting point. Therefore the dynamics of the object is multistable.

The object's motion can be understood using the physical concept of energy. Because the gravitational potential energy of the object is a linear function of its height, the surface can be regarded as a graph of energy versus location in the horizontal plane. The object behaves as if its goal were to minimize its potential energy, in the sense that its downhill motion causes

In an influential paper published in 1982, John Hopfield constructed a mathematical function that assigns a numerical value to any activity pattern of a neural network model. He proved mathematically that this number is guaranteed to decrease as the activity of the network evolves in time until a stable state is reached. Because of this property, Hopfield's function represents the "energy of the network," and we will call it an *energy function*. The energy of the network is analogous to the height of the sliding object in Figure E-7, and the activity of the network is analogous to the horizontal location of the sliding object. Of course, Figure E–7 is an impoverished depiction of a network energy function because the activity pattern of a network of n neurons is an n-dimensional vector, not a two-dimensional location in the horizontal plane.

As a special case, Hopfield applied the energy function to associative memory networks, showing that the process of memory recall by pattern completion (Figure E–5) is analogous to an object sliding down an energy landscape (Figure E–7).

Hopfield's construction of the energy function required that the interactions between neurons be symmetric: Any connection from one neuron to another is mirrored by another connection of equal strength in the opposite direction. This is the case, for example, in the cell assemblies of Figure E–5. Although perfect symmetry of interactions is not biologically plausible,

the potential energy to decrease until a minimum is reached. The multiple stable states correspond to the multiple minima of the energy.

⁵Some apply the term *attractor network* rather loosely to any recurrent network, whereas others restrict application to recurrent networks with multistability.

⁶It should be stressed that this is an analogy, that the energy function is distinct from energy in the sense of physics. A minimum of the network energy function might actually correspond to an activity pattern in which neurons are firing at high rates and using large amounts of energy.

approximate symmetry might be a property of some biological neural networks, so that Hopfield's networks might be regarded as an idealization of them.

In 1986 Hopfield and David Tank pointed out that a neural network with an energy function can be used to perform a type of computation known as optimization. Many interesting problems in computer science can be formulated as the optimization of some kind of function. For example, in the traveling salesman problem, a salesman would like to find the shortest route by which he can visit multiple cities and return to his starting point. In this problem the function to be optimized is the length of the route. Hopfield and Tank showed how to construct a network that finds solutions to the traveling salesman problem. The energy of their network is equal to the distance of the route, which is encoded by the activity of the network. Because the network converges to a minimum of the energy, it effectively searches for an optimal solution to the traveling salesman problem.

This general approach was applied by many others to construct neural networks that solve a variety of optimization problems. The Hopfield-Tank approach could be viewed as an extension of the cell assembly to a general method of encoding a computational problem in the connections of a recurrent network, which solves the problem by converging to a steady state.

Hebbian Plasticity May Create Sequential Synaptic Pathways

In the simulations in Figure E–5 it is assumed that synapses between pairs of neurons are strengthened when the two neurons are active simultaneously. If signaling flows in both directions between the neurons, the synapses in both directions will be strengthened, preserving the symmetry of the interactions between the neurons.

However, Hebb actually argued that a synapse is strengthened when the presynaptic neuron is activated immediately before the postsynaptic neuron (activity in the presynaptic cell leads to an excitatory postsynaptic potential that contributes to firing the postsynaptic action potential). Hebbian plasticity that depends on temporal order has been observed in spike timing-dependent plasticity (see Chapter 67). The temporal asymmetry of this learning rule can lead to synaptic connectivities that are asymmetric, as opposed to those shown in Figure E–5.

Such asymmetry in the connectivity could be appropriate for the storage and recall of motor sequences, needed in skills such as playing a musical instrument, and which consist of temporally structured steps.

Motor sequences are presumably created by sequential activation of groups of neurons. One can imagine storing a sequence in a network by giving it extrinsic inputs that activate neurons in some order. Hebbian plasticity would lead to a set of strengthened connections that are organized like the perceptron of Figure E–1. Later on the sequence could be recalled by activating the first group of neurons, which would activate the second group, and so on. The network would generate the sequence that had been stored by extrinsic input. This would be another example of pattern completion, one in which the pattern is a temporal sequence rather than a stable state as in Figure E–5.

In this hypothetical example the strong connections all point in the same direction, so that the interactions in the network are asymmetric. The network is unable to generate the same sequence in the opposite order because of the asymmetry. This is consistent with the fact that many well-practiced motor sequences are difficult to carry out in reverse order.

It seems plausible that symmetric and asymmetric connections could be important for storing different types of associations. The memory of a telephone number is sequential and asymmetric; remembering it forward is much easier than trying to remember it backward. But other types of associations are more symmetric: A face may evoke a name as easily as a name evokes a face.

In associative memory networks long-term memories are stored through modifications of synaptic strengths that last for long times. But such Hebbian style long-term potentiation is just one type of modification of biological synapses (see Chapter 67). The strengths of biological synapses can change more transiently. Diverse types of transient modification—short-term facilitation, short-term depression, augmentation, and so on—have been classified by their time scales and other properties. It is natural to speculate that these different forms of synaptic alteration could be used by the brain for a whole spectrum of memory processes with different time scales. In this view a firm distinction between short-term and long-term memory is too simplistic.

Previously we explained that a cell assembly supports both short-term and long-term memories. Does this mean that one can only maintain short-term memories of items that have already been stored as long-term memories? Everyday experience suggests that one can briefly maintain a short-term memory of a telephone number that has never been encountered before, for which no long-term memory exists. This issue could perhaps be solved if, as suggested above, the sharp distinction between short-term and long-term memory

were replaced by a spectrum of memory processes with different time scales.

As noted in the introduction, the idea that persistent activity is maintained by cell assemblies, or more generally by synaptic loops, dates back to Hebb and Lorente de Nó. Many researchers have developed detailed and realistic simulations based on this idea, simulations that are more convincing than the simple one shown in Figure E–5. But demonstrating empirically that a specific example of persistent activity in the brain is caused by synaptic loops has been difficult. Persistent activity could also arise as an intrinsic property of the biophysics of single neurons, rather than an emergent property of networks. Hence the biological mechanisms of persistent activity are still controversial.

An Overall View

Perceptrons and associative memory networks are two historic types of neural network models still in use today. A perceptron is a layered network with no synaptic loops. Its layers represent sequential steps of a computation, where each layer can be regarded as many operations performed in parallel. The visual system has been modeled as a perceptron in which neurons are feature detectors and are hierarchically organized. According to this hierarchical perceptron model, visual recognition of an object is a sequential process in which each step consists of many feature detection events executed in parallel.

Because perceptrons lack synaptic loops, their dynamical behaviors are relatively simple. But the dynamics of the brain can evolve in ways that are dissociated from immediate sensory stimuli or motor actions. These rich intrinsic dynamics are likely to depend on loops in the synaptic connectivity of the brain. Hebbian plasticity is thought to create cell assemblies, which contain synaptic loops. These loops can endow a neural network with the property of multistability, and also lead to persistent activity patterns resembling those observed in neurophysiology experiments on short-term memory. Finally, symmetric neural networks, which contain synaptic loops, have been used to solve optimization problems and could therefore be viewed as a general class of computational devices.

Although decades have passed since perceptrons and associative memory networks were invented, it is still unclear how well these models explain visual perception and the storage and recall of memories. Given that these are some of the deepest and most complex issues in neuroscience, perhaps it is not surprising

that testing the models experimentally is difficult. But given today's rapid progress in developing new experimental methods, one could imagine that neural network models will eventually come to play as central a role in systems neuroscience as the Hodgkin-Huxley model of the action potential plays in cellular neurophysiology.

Recurrent Networks Can Model Decision-Making

IN ONE WAY OR ANOTHER ALL scientific researchers construct models. The role of theory is to develop, refine, and investigate these models to uncover new insights and to make new predictions. Theoretical (or computational) neuroscience explores the application of mathematical and computational methods to the study of neural systems.

Defining models of neural systems in mathematical terms assures that the models are self-consistent, with clearly revealed assumptions and limitations.

Formulating models mathematically also allows the powerful techniques of mathematics and physics and the extraordinary capacity of modern computers to be used to understand model behavior. This power allows the implications of the models to be worked out fully, revealing features that are surprising and nonintuitive.

What makes a model good? Clearly it must be based on biological reality, but modeling necessarily involves an abstraction of that reality. It is important to appreciate that a more detailed model is not necessarily a better model. A simple model that allows us to think about a phenomenon more clearly is more powerful than a model with underlying assumptions and mechanisms that are obscured by complexity. The purpose of modeling is to illuminate, and the ultimate test of a model is not simply that it makes predictions that can be tested experimentally, but whether it leads to better understanding. No matter how detailed, no model can capture all aspects of the phenomenon being studied. As theoretical neuroscientist Idan Segev has said, borrowing from Picasso's description of art, modeling is the lie that reveals the truth.

Appendix E introduced two ideas that are central in theoretical neuroscience: the perceptron and the attractor. In this appendix we extend the discussion of theoretical neuroscience by considering the effect of synaptic input on neuron models that produce action potentials, by showing how inhibition and excitation can interact in network models to produce interesting and nonintuitive effects, and by presenting a model of decision-making. These examples convey a sense of how theoretical neuroscience research is done, and how it can shed light on the types of computations that neurons and networks of neurons can perform.

Single-Neuron Models Allow Study of the Integration of Synaptic Inputs and Intrinsic Conductances

Models of single neurons include some of the most detailed, accurate, and complex simulations performed in the field of theoretical neuroscience. Single-neuron modeling is used to reveal how the many different voltage- and ligand-dependent conductances expressed by a neuron interact to generate patterns of activity ranging from transient and sustained firing to the production of subthreshold oscillations and action-potential bursts. Because membrane conductances are nonlinear, interactions between them can be complex. Modeling studies allow these interactions to be mapped out and understood.

Another major focus of single-neuron modeling is to understand the functional consequences of the complex and beautiful morphology of neurons. One goal of this work is to understand how the specific location of a synapse or group of synapses on the dendritic arbor, in interaction with the voltage-dependent conductances in dendrites, affects the efficacy of synapses to drive a neuron to fire. Synaptic plasticity is also a major target of dynamically detailed modeling of neurons. In this regard backpropagating action potentials, which provide information to the synapses about the timing of somatic action potentials, are of particular interest. This work, and of course its experimental counterpart, has revealed the roles of nonlinear summation, subthreshold boosting, and dendritic spiking in the integration of inputs across the dendrite.

Single-neuron modeling studies are also valuable for understanding the effects of complex patterns of synaptic inputs on neuronal activity. In an experimental setting it is difficult to control large numbers of synaptic inputs precisely enough to perform analogous studies. Neurons are often studied in fairly inactive tissue slices or isolated in cell cultures. In vitro experiments can tell us how a particular neuron responds to the activation of one or a few synapses (from paired recordings, for example) or to synchronous activation of many synapses (through extracellular stimulation). Studying neurons with controlled synaptic input is ideal for exploring their basic electrophysiological characteristics, but not for understanding how they operate in vivo. We typically want to know how the neuron reacts to the complex input patterns that it receives from thousands of afferent fibers in a live animal. Theoretical studies allow us to bridge the gap between what we know from reduced experimental protocols and what we need to know to understand

functioning neural circuits: the response properties of neurons in their natural environment.

Appendix E considered a neuron model in which synchronous presynaptic action potentials are counted and compared with a threshold to determine output. Here we examine how the large quantity of constant synaptic input in vivo modifies this picture, focusing on the effects of synchronization and timing of presynaptic inputs on the response of a neuron. Action potentials are also known as *spikes*, and we use the two terms interchangeably.

The role of spike synchronization in neural coding and signaling is actively debated. Synchronization of spikes has been proposed as a mechanism by which attention might enhance signals of particular interest, based on the observation that synchronous action potentials drive a neuron more strongly than the same number of action potentials spread over time. However, it is unlikely that all inputs to a neuron would ever be synchronized. Instead, we assume that the neuron receives a "background" of many asynchronous inputs, and that a small number of these inputs, which we call the signaling inputs, become synchronized by a particular signal or drive. Thus we need to study the effects of various degrees of synchronization in subsets of signaling inputs in a background of asynchronous input. Studying the effects of spike timing in more realistic conditions allows us to assess more accurately the role that timing may play in neural coding of information and in synaptic plasticity.

We will compare the sensitivity of neurons to the numbers and timing precision of synchronous signaling inputs in a quiet slice-like setting and in an active environment of asynchronous background inputs resembling that found in vivo. We will use a simple but useful model of the postsynaptic neuron known as the *integrate-and-fire model* in which inputs are integrated until a threshold voltage is reached, at which point a spike is emitted and the voltage is then reset to a lower value (Box F–1). By studying the responses of this model neuron we can compare the impacts of spike synchronization with and without asynchronous background input.

Neurons Show Sharp Threshold Sensitivity to the Number and Synchrony of Synaptic Inputs in Quiet Conditions Resembling In Vitro

We first explore the sensitivity of our integrate-and-fire model neuron to the number of synchronous signaling inputs it receives in the absence of any background asynchronous input. Under these conditions 43 synchronous presynaptic inputs are required to elicit an action potential (Figure F–1A).

Box F-1 The Integrate-and-Fire Model

The integrate-and-fire model is a model of real neurons that is simplified in three essential ways. It consists of a single compartment (typically only a cell body); its relationship between membrane current and membrane potential is linear; and it fires action potentials through a threshold-crossing rule.

Nevertheless, the model captures three essential features of the biophysics of neurons: membrane resistance, membrane capacitance, and action potential generation. In the model the membrane potential V for a neuron receiving a synaptic current I is governed by the equation

$$C_{\rm m} \frac{dV}{dt} = \frac{V_{\rm rest} - V}{R_{\rm m}} + I$$
 (F-1)

where $C_{\rm m}$ is the membrane capacitance, $R_{\rm m}$ the membrane resistance, $V_{\rm rest}$ the resting potential of the neuron,

and I the current arising from synaptic inputs. This is the same equation used in Chapter 6 to describe passive changes in the membrane potential of a neuron.

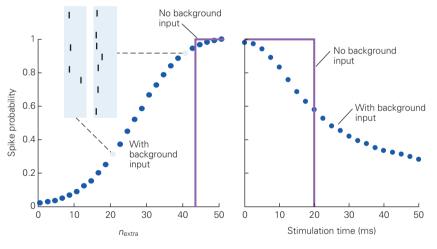

Action potentials are generated by augmenting the equation with a rule: When the membrane potential reaches a threshold value, $V_{\rm th}$, an action potential is generated and the membrane potential is reset to a value $V_{\rm reset}$. After this the membrane potential is held at $V_{\rm reset}$ for a refractory period and then released to obey Equation F–1 once more.

To generate spontaneous background synaptic input in the single-neuron model, *I* is modeled to duplicate the effects of a large population of excitatory and inhibitory synapses being activated by constant-rate Poisson spike trains. For the network example, *I* for each neuron represents synaptic currents activated by other neurons in the network.

A Variable number of synchronous inputs

B 50 inputs spread over variable times

C Background inputs alone

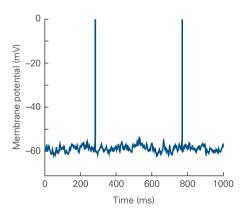

Figure F–1 Responses of an integrate-and-fire model neuron to synchronous input.

A. The plot shows the probability of a postsynaptic action potential or spike in response to synchronous input from $n_{\rm extra}$ excitatory synapses, both with and without any background (asynchronous) synaptic input. Without background input there is a sharp threshold: 42 synchronous inputs never give a spike, whereas 43 such inputs always do. With background input there is a much more gradual change in spike probability with the number of synchronous inputs and an increased sensitivity to small numbers of such inputs. The inset shows sample raster plots of postsynaptic spikes from 10 trials in the presence of background input plus either 20 synchronous excitatory synapses (left) or 40 (right). (Each row represents one trial; each vertical dash represents the time of occurrence of a postsynaptic action potential.)

B. The plot shows the probability of a postsynaptic action potential being generated by 50 signaling inputs with varying degrees of synchrony. Spreading the inputs uniformly over the stimulation time varies the degree of synchrony. With no background synaptic input there is a sharp threshold, so that if all inputs fire within 20 ms they always generate a spike; otherwise they never do. With an asynchronous background the transition is much more gradual, so that even with relatively little synchrony there is a significant probability of evoking a spike.

C. Asynchronous background input alone drives a low level of firing even in the absence of any signaling input, as seen by the two spikes that occur in the 1 second sample trace. The peaks of the action potentials have been clipped at 0 mV.

The number 43 depends on the particular model parameters we have chosen, but a more general property is also revealed. For the model in Appendix E the probability of producing a spike rises as a sharp step from 0 to 1, meaning that fewer than 43 synchronous presynaptic action potentials will never produce a response, whereas 43 or more will always produce a postsynaptic spike. Thus, when synchronous input appears alone without any asynchronous inputs, the neuron has a sharp threshold sensitivity to the number of synchronous action potentials it receives.

How sensitive is the neuron to timing of the signaling synaptic inputs? To address this question we look at what happens when the synchronous action potentials are spread over a finite period of time, thereby slightly desynchronizing them. When 50 input spikes are spread evenly over intervals ranging from zero to 50 ms, the model neuron responds only if the 50 input spikes are contained within an interval of 20 ms or less (Figure F–1B), indicating that it is quite sensitive to the interval over which the 50 input spikes are spread. Not surprisingly, the 20 ms interval matches the membrane time constant of the model neuron. Thus in the absence of asynchronous input this model neuron is highly sensitive to both the number and timing of its synchronous or nearly synchronous inputs.

Neurons Show Graded Sensitivity to the Number and Synchrony of Synaptic Inputs in Noisy Conditions Resembling In Vivo

What is the effect of background synaptic activity on the sensitivity of a neuron to synchronous signaling input? To address this question we again introduce either synchronous or slightly desynchronized signaling input, but this time we add it to ongoing asynchronous background input.

The nature and impact of ongoing background activity, which varies across brain areas, is a subject of intense experimental and theoretical investigation. Experiments that use different recording techniques do not always agree on the spontaneous firing rates even of neurons in the same area, and conflicting values are reported for the total synaptic conductance produced by spontaneous activity. Nevertheless, in studies of the cerebral cortex all researchers agree that background activity is large enough to cause significant fluctuations in the membrane potentials of recorded neurons, sometimes large enough to drive firing.

The background synaptic input we are discussing contains both excitatory and inhibitory components. In some cortical areas the background input appears as occasional bursts amidst relative quiet. In many other cortical areas the background input drives constant, ongoing voltage fluctuations. In these areas there is evidence that the excitatory and inhibitory components are individually quite large but roughly balance or cancel each other out. This cancellation is subject to fluctuations in which excitatory or inhibitory drive momentarily dominates. In the next section we illustrate how a network of deterministic model neurons can generate such fluctuations spontaneously. Here we obtain similar fluctuations by randomly generating presynaptic action potentials.

Ongoing background activity affects how a neuron integrates its signaling inputs. It also acts as a source of noise that usually limits, but in some cases enhances, the sensitivity and precision of responses to signaling inputs. For the single-neuron model we are using the asynchronous background synaptic input has three primary impacts. First, it alters the neuronal membrane potential, in our case raising it from a resting value of 20 mV below threshold to approximately 5 mV below threshold. This effect is caused by the fact that the cancellation or balance between excitation and inhibition is, even on average, only approximate. Because the model neuron is now closer to threshold, it becomes more sensitive to additional input.

Second, the continual activation of both excitatory and inhibitory synaptic conductances by ongoing input increases the overall conductance of the neuron. This lowers its effective time constant, allowing for quicker responses, and also reduces the sensitivity of the neuron to other synaptic input. However, for our model parameters the lowering of sensitivity is more than compensated by the fact that the baseline membrane potential is raised by 15 mV.

Third, background synaptic input introduces fluctuations in the membrane potential that generate a low rate of background firing and add a level of noise to responses to signaling inputs (Figure F–1C).

To study the effect of synchronous signaling input in the presence of this background, we add a number of extra presynaptic spikes at a particular point in time. The addition of 20 synchronous spikes produces a post-synaptic response on 4 out of 10 trials, whereas adding 40 synchronous inputs generates a spiking response on 7 of 10 trials (Figure F–1A). By accumulating results like these over many repeated trials, we can determine how often (on what fraction of trials or, equivalently, with what probability) a postsynaptic action potential is evoked within a short time interval (10 ms) following the synchronous presynaptic input.

Recall that in the absence of background input the model neuron showed sharp threshold sensitivity to the number of synchronized input spikes. This sharp threshold is lost when background input is added, but it is replaced by a higher sensitivity to small numbers of synchronized presynaptic action potentials (Figure F–1A). Rather than requiring at least 43 synchronous excitatory inputs to generate an output, the probability that the neuron will fire in the presence of background activity rises smoothly from zero. The neuron has a significant probability of responding to as few as 10 synchronous presynaptic action potentials.

Ongoing asynchronous background input also alters the probability of evoking a postsynaptic action potential when presynaptic action potentials are not perfectly synchronous but are spread uniformly over a finite stimulation time. Just as the neuron lost its step-like threshold for the number of presynaptic action potentials required to elicit a spike, it also loses its sharp sensitivity to the relative timing of these inputs (Figure F–1B). The neuron responds approximately 30% of the time to 50 additional action potentials even when they are spread over 50 ms. Thus the results in Figures F–1A and F–1B show that background input makes the neuron more sensitive to small numbers of presynaptic spikes but less sensitive to their synchrony (the degree to which they are tightly grouped in time).

Neuronal Messages Depend on Intrinsic Activity and Extrinsic Signals

The issue of whether to think of spike timing or firing rates as the dominant carrier of the "neural code" has been debated extensively, but it is often difficult to understand exactly what is being debated. Action potentials in a particular pathway carry information by virtue of their times of occurrence; they have no other attribute that can be varied systematically.

A steady signal can be adequately represented by neuronal firing rates because there is no temporal structure for spike times to encode. For rapidly fluctuating signals, however, spikes times can be important because they carry information about the timing and amplitude of such fluctuations. Either way we must remember that neurons respond in the context of the active environment in which they operate.

As we see from Figure F–1, inferences made from observations of neurons in a silent environment (without background synaptic input) may underestimate the responsiveness of a neuron to weak excitation. Similarly the ability of the neuron to sharply delineate different levels of input may be overestimated and the neuron's sensitivity to spike timing exaggerated.

Network Models Provide Insight into the Collective Dynamics of Neurons

Models of networks of neurons, or neural circuits, help us understand how large populations of neurons can work together to perform tasks. Using models, theorists have learned how networks can sustain particular patterns of *reverberating* activity or generate oscillatory or chaotic firing.

Network models address such issues as how neurons in primary sensory areas produce their responses, how cortical maps form and are modified by sensory experience, how populations of neurons represent information collectively and combine multisensory data, how objects are identified and classified, how memories stored in modified synaptic strengths can be read out, how motor responses are generated, and how evidence is integrated and used to make decisions.

Appendix E discusses basic ideas of how feed-forward circuitry (circuitry with no synaptic loops) may underlie the response properties of simple and complex cells in the primary visual cortex, and how recurrent circuitry (circuitry with synaptic loops) can create a *cell assembly* with strong mutual excitation among its neurons, allowing the assembly's activity to persist in the absence of a stimulus (thus forming an *attractor*). Here we continue these discussions with examples from network modeling.

We will examine how recurrent loops change both the gain and dynamics of responses to inputs, how a fully recurrent network can have hidden within it an effectively feed-forward structure that allows changes in gain to be separated from changes in dynamics, and how these ideas can give insight into aspects of visual cortex function. We also show how the basic idea of attractors can be extended to create a model of decision-making. Before we consider these examples, we show what can happen when model neurons like the one discussed previously are linked together into a network.

Balanced Networks of Active Neurons Can Generate the Ongoing Noisy Activity Seen In Vivo

When constructing and analyzing large networks it is typically not practical to model the constituent neurons with a high level of detail. Instead, the multitude of synaptic conductances and the complexity of dendritic morphology seen in real neurons are usually distilled down to a bare minimum.

In network models individual neurons are often modeled as integrate-and-fire neurons (see Box F-1)

but may also be modeled as *firing-rate neurons*, meaning that only the rate at which a neuron fires is modeled, and not the timing of individual spikes (Box F–2). We employ both neuron models here. Simplifying the descriptions of individual neurons allows us to focus on effects that arise through network interactions.

What happens if we link together a large number of integrate-and-fire neurons through excitatory and inhibitory synapses? Such models typically involve thousands or even hundreds of thousands of neurons connected randomly and sparsely so that the probability of any two neurons being connected is less than 10%. Excitatory and inhibitory neurons are included in roughly the 4:1 proportion seen in cortical circuits.

The activity in such networks takes a number of different forms as shown by Carl van Vreeswijk and Haim Sompolinsky and by Nicolas Brunel. When the synaptic connections are weak, the bulk of the neurons are silent; but some fire in steady, regular sequences of action potentials that are not synchronized with the activity of other neurons of the network (Figure F–2A). As the strengths of the synapses, both excitatory and inhibitory, are increased, the network can transition into a state where the silent neurons start to fire, and the action potentials appear in irregular, asynchronous patterns (Figure F–2B). This form of activity provides a model of the background activity seen in real neural circuits.

The irregular, asynchronous activity depends on the sparseness of the synaptic connections in the network and on a balance between excitatory and inhibitory inputs received by a cell. These inputs arise from many other excitatory and inhibitory neurons that are themselves firing irregularly. Overall these inputs are balanced—on average, excitation and inhibition cancel—but constant fluctuations in input drive the cell to fire at irregular times. Thus the network self-consistently maintains irregular firing in all of its neurons. If the balance of

Box F-2 Firing-Rate Models

A network in which neurons and the interactions between them are described in terms of firing rates has two critical elements. The first is the relationship between the total synaptic current I that a neuron receives and its firing rate r. For current that is constant, this relationship is given in terms of a firing-rate function, r = F(I).

When the current varies with time we assume that the firing rate lags behind but approaches this function exponentially, with a time constant τ , so that

$$\tau \frac{dr}{dt} = -r + F(I).$$

because this is a considerable simplification in the transformation from spiking to firing rate, the time constant τ does not have a straightforward biophysical interpretation and must represent the temporal response properties of the system as a whole, including (but not limited to) the effects of both membrane and synaptic time constants.

The second element needed to construct a network model is the relationship between *I* and the activity of other neurons in the network. The total current for each neuron is the sum of terms representing each of its inputs. The contribution of an individual presynaptic neuron to *I* is given by the product of its firing rate and a weight factor that characterizes the strength and type of the synapse through which it acts. The weights for excitatory

synapses are positive whereas those for inhibitory synapses are negative.

If the network we are studying receives input from other areas outside the local network, this is included as an additional term in I that we denote by h.

As an example of a firing-rate model, consider a network of two populations of cells. A population of excitatory neurons all fire at a rate $r_{\rm E}$ and a population of inhibitory neurons fire at rate $r_{\rm I}$. The external inputs to these two populations are denoted by $h_{\rm E}$ and $h_{\rm I}$.

The strength of the synaptic connections between neurons of the excitatory population is denoted by $w_{\rm EE}$, that between the inhibitory neurons by $w_{\rm II}$, and the connections from the excitatory to the inhibitory and from the inhibitory to the excitatory populations have strengths given by $w_{\rm IE}$ and $w_{\rm EI}$, respectively.

The resulting equations for the firing rates of the two populations are

$$\tau_{\rm E} \frac{dr_{\rm E}}{dt} = -r_{\rm E} + F(w_{\rm EE}r_{\rm E} - w_{\rm EI}r_{\rm I} + h_{\rm E})$$
 (F-2)

$$\tau_{_{\rm I}} \frac{dr_{_{\rm I}}}{dt} = -r_{_{\rm I}} + F(-w_{_{\rm II}}r_{_{\rm I}} + w_{_{\rm IE}}r_{_{\rm E}} + h_{_{\rm I}}).$$
 (F-3)

Equations similar to these were used for Figures F–3, F–5 through F–7, and in Box F–3.

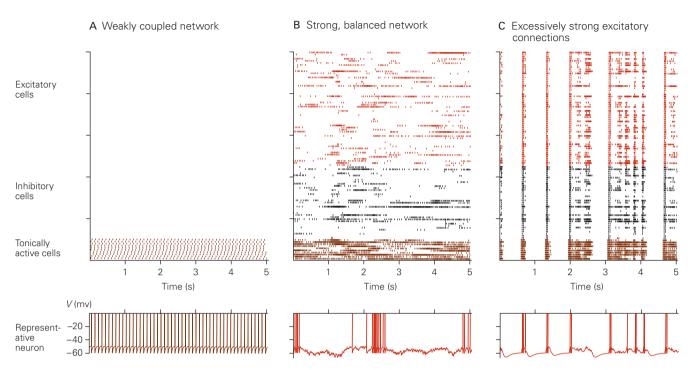

Figure F-2 Activity in networks of spiking neurons. The raster plots show a representative sample of neurons in a network of integrate-and-fire model neurons (only a fraction of network neurons are shown). Each row is a separate neuron, and each dot in a given row represents an action potential fired by that neuron. The voltage traces below the raster plots show a single representative neuron. The trace in part A denotes a tonically active excitatory neuron, while the traces in parts B and C are for nontonically active excitatory neurons. A tonically active neuron is one that receives a constant input current in addition to input from the network but is otherwise identical to the other excitatory neurons. The peaks of the action potentials are clipped at 0 mV.

Individual neurons may fire at regular intervals (regular firing) or at random times (irregular firing). In addition, neurons tend to fire independently rather than synchronizing their spike times (asynchronous firing).

A. In a weakly coupled network the tonically active neurons show regular asynchronous firing while all other neurons are silent.

B. A network with strong but balanced excitation and inhibition exhibits irregular, asynchronous spiking.

C. A network with excessively strong excitation shows seizure-like activity with the synchronous firing of a large fraction of the neurons.

excitation and inhibition is not maintained, a network-model form of epilepsy can arise (Figure F–2C). In this case the asynchronous activity is interrupted by gaps and periods of synchronous firing across the population. It is interesting that network models of ongoing spontaneous activity suffer quite easily from seizure-like activity, just like real neural circuits.

Irregular, asynchronous firing, much like the background firing seen in many cortical areas, can arise in network models with different patterns of synaptic connectivity, such as when the probability of connection between two neurons decreases with the distance between them or with the difference between their selectivities to stimulus properties. The major requirement is that inhibition must balance excitation, so that the mean input cannot drive the cell to fire and instead

firing is induced by input fluctuations. In addition, connectivity should be sparse so that the firing of different cells does not become synchronized.

What can structured network circuitry achieve? In the following discussion we provide a few illustrative answers to this question. For this analysis we switch from a network of spiking model neurons to one in which the activities of network neurons are described by firing rates (Box F–2). Networks of spiking model neurons can display patterns of activity that cannot be reproduced by firing-rate models, but there is good agreement between the two types of models for the steady-state asynchronous activity we discuss here and in the following sections. Describing neuronal responses in terms of firing rates makes the mathematical analysis of neural networks much easier.

Feed-forward and Recurrent Networks Can Amplify or Integrate Inputs with Distinct Dynamics

The relative roles played by feed-forward and recurrent circuitry in shaping neuronal responses is a subject of debate in neuroscience. For example, neurons in layer IV of the primary visual cortex receive afferent inputs from the lateral geniculate nucleus of the thalamus, which relays visual information from the eyes, but they also receive abundant innervation from other cortical neurons. Are the tuning properties of these neurons—the dependence of their firing rates on stimulus parameters such as the orientation of a light or dark edge—determined mainly by feed-forward input from the lateral geniculate nucleus, or are they strongly shaped by recurrent cortical feedback?

The answer is not immediately obvious because feed-forward circuits and circuits in which tuning is strongly shaped by recurrence (recurrent networks) can produce the same types of response selectivity or tuning. Intracellular recording in vivo, in which voltage responses and their changes under experimental perturbations are studied, can more clearly distinguish the two types of circuits. However, given only firing rate responses, the differences between feed-forward and recurrent circuits are easiest to detect by examining response dynamics rather than static response properties. For this reason, here we discuss the dynamics of network responses in various forms of feed-forward and recurrent circuits.

A feed-forward circuit can modify input signals, creating a wide variety of response selectivities or amplifying a weak input without significantly altering response dynamics. For example, if one set of neurons forms strong excitatory synapses with another set, a weak input to the first set can yield a strong response in the second. This occurs with only a small dynamic change, namely the small delay required for the first set of neurons to integrate the input and produce spikes that propagate to drive the second set of neurons.

Similarly, recurrent circuits can modify input signals, but typically with larger dynamic changes. An example of this is a circuit that amplifies its inputs through recurrent excitatory loops. Consider a population of neurons that excites itself. The population's response to an external input can be significantly amplified because the recurrent excitation adds to the external drive. However, unlike feed forward amplification the recurrent excitation is accompanied by a general slowing of the population's response dynamics, which arises as follows.

A population responds to a pulse of input with a pulse of activity that then decays away. The recurrent

excitation adds back some of the activity that would otherwise decay, slowing the decay of the population's activity. The population's response to a sustained input is similarly slowed; the ultimate response to input is amplified by a factor roughly equal to the degree of slowing (ie, a threefold slowing yields a threefold amplification) (Figure F-3A). This can be understood by thinking of the sustained input as a continuous sequence of pulse inputs. We imagine that the response to the sequence of pulses is just the sum of the responses to each individual pulse. (This is not quantitatively correct but provides a useful qualitative representation.) Because individual pulse responses decay more slowly, the overall level to which they sum is increased, but the rise of activity to this level occurs more slowly.

A network with recurrent excitation and inhibition can also have inhibitory loops through which a population of neurons inhibits itself. In this case responses are sped up rather than slowed down, and they are reduced in amplitude (Figure F–3B). The reduction in response amplitude occurs because the decay of the response to a pulse of input is accelerated: In addition to the decay that would otherwise occur, inhibition subtracts even more from the activity. Because the responses to individual pulses decay more quickly, the overall level to which they sum is decreased, but the rise of activity to this level occurs more quickly.

If recurrent excitation is increased to the point where activity set up by a transient input can sustain itself indefinitely, decay does not occur at all and the response is infinitely slowed. This requires fine-tuning of network parameters. The resulting circuit, known as an *integrator network*, has some interesting properties. The response of an integrator network to a transient pulse of input is a change in firing rate that lasts forever in the absence of further input but which becomes part of an ongoing integral if further input is applied (Figure F–3C). If the transient excitation in the network is not perfectly tuned but instead is slightly weaker, the input produces a change in firing rate that decays very slowly. Such approximate integrators are used to model neural circuits that remember signals.

What happens if the amount of excitation is increased beyond the point of perfect tuning that achieves an integrator? The examples shown in Figure F–3 all start and end in a resting state with zero activity. When excitation is overly strong, such a resting state, whether or not it is characterized by zero activity, becomes unstable. This means that after any small perturbation, induced for example by a transient input, the system will drive itself further away from this state rather than relaxing back to it.

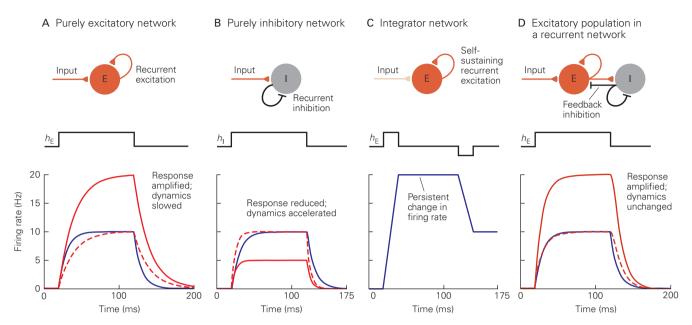

Figure F-3 Responses in excitatory and inhibitory networks of firing-rate neurons.

- A. Response of a purely excitatory recurrent network to a square step of input ($h_{\rm E}$). The **blue curve** is the response without excitatory feedback. Adding recurrent excitation increases the response but makes it rise and fall more slowly (**solid red curve**). The **dashed red curve** is a smaller copy of the solid red curve (scaled by a factor of 0.5) so that the time course of the solid red and blue curves can be compared more easily.
- **B.** Response of a purely inhibitory recurrent network to a square step of input (h_l) . The **blue curve** shows the response without recurrent inhibition. Adding recurrent inhibition decreases the response but makes it rise and fall more rapidly (**solid red curve**). The **dashed red** curve is a larger (2X) copy of the solid red curve.
- **C.** Response of an integrator network to two input pulses $(h_{\rm E})$. The response is the integral of the input and remains constant when the input is not present.
- D. Response of the excitatory population in a mixed excitatory/ inhibitory recurrent network to input to the excitatory neurons (h_E). The excitatory population excites both itself and the inhibitory population, whereas the inhibitory population inhibits both itself and the excitatory population, thus providing feedback inhibition to the excitatory population. The blue curve shows the response without recurrent connections (ie, without recurrent excitation or feedback inhibition). Adding the excitatory and inhibitory recurrent connections increases the response amplitude with little change in its time course (solid red curve). The dashed red curve is a scaled copy of the solid red curve as in part A.

Nonlinear processes ultimately stabilize a new pattern of activity, which is determined primarily by the network's own recurrent excitation rather than by the input and which can be self-sustaining in the absence of an input.

Fixed patterns of activity established and maintained by recurrent circuitry are attractors, as described in Appendix E. Attractors are often used as models for the persistent neural activity thought to hold items in working memory. If many different activity patterns are each strongly self-excitatory, a network can generate far more complex, chaotic dynamics. It has been argued that this can create a rich set of temporal patterns in areas of cortex such as primary motor cortex that can be harnessed by signals from motor planning areas to drive complex movement patterns.

Balanced Recurrent Networks Can Behave Like Feedforward Networks

Anatomical and electrophysiological studies of neurons in layer IV of the primary visual cortex (and in other sensory areas) have revealed many more recurrent than feed-forward connections in this layer. This discovery might seem to rule out feed-forward networks as relevant models of cortical circuits. However, function need not follow numbers.

A prominent hypothesis, supported by considerable evidence, is that the feed-forward inputs provide the driving input to layer IV neurons while the recurrent inputs amplify and modulate but do not drive responses. Feed-forward circuits are also relevant in another way: Under appropriate circumstances,

strongly recurrent circuits can act effectively in a feedforward manner.

To see how this works, we study a network consisting of two coupled populations, one excitatory and one inhibitory. To simplify the discussion we let the two projections from the excitatory population (to itself and to the inhibitory population) have the same strength, and likewise the two inhibitory projections. Thus we can speak of the strength of excitation (or inhibition)—meaning excitation (or inhibition) onto both excitatory and inhibitory neurons—without having to distinguish multiple projections of each type. Although this simplification dictates the specific results, it does not affect the overall conclusions as to how recurrent circuits can act in a feedforward manner and thus dissociate amplification from changes in dynamics.

We suppose the network is at a fixed point, meaning that there are steady excitatory and inhibitory firing rates in response to a steady feed-forward input, and that this fixed point is stable-after small transient perturbations the network will return to the fixed point. We suddenly increase the level of feed-forward input to the excitatory population (Figure F-3D). In this recurrent network the excitatory activity is amplified by the recurrent circuitry. Surprisingly, however, the time course of the increase is little different from that without recurrent circuitry. With different parameters the recurrently amplified response can exactly match the timing of, or even be faster than, the response without recurrent circuitry. Thus the recurrent circuit can amplify responses without any slowing of the temporal dynamics.

Apparently the mechanism of amplification is different from the recurrent amplification we considered previously. What is this mechanism? At the fixed point the difference between the excitation and inhibition received by a population is exactly that required to sustain the population's firing rates. Any change in the balance between excitation and inhibition drives a change in the firing rates until a new balance is restored. Increasing the feed forward input to the excitatory population shifts the balance toward excitation, thus driving up both excitatory and inhibitory firing rates. Similarly, an excess of inhibition drives down both excitatory and inhibitory firing rates.

Let us represent the firing rates as differences from the fixed-point firing rates. In this representation firing rates may be either positive or negative. We can then formally represent any pattern of excitatory and inhibitory firing rates as a weighted combination of two activity patterns. In the differential pattern excitatory and inhibitory cells have equal and opposite firing rates. In the common pattern excitatory and inhibitory

cells have identical firing rates. Given some excitatory and inhibitory firing rates, if we weight the common pattern so that its common firing rate is the average of the excitatory and inhibitory rates, and weight the differential pattern so that it captures the difference between excitatory and inhibitory firing rates, then the sum of the two weighted patterns equals the given firing rates.

The advantage of expressing the activities in terms of these two patterns is that it allows a deeper insight into the dynamics. A shift in the network's balance toward excitation involves an increase in the size of the differential pattern, that is, the signed difference between excitatory and inhibitory firing rates increases. This imbalance in turn drives an increase in the size of the common pattern, that is, both excitatory and inhibitory firing rates increase. Similarly, a shift in the balance toward inhibition involves a decrease in the differential pattern, which decreases the common pattern. The network thus behaves precisely as it would if the differential activity pattern made a feedforward synaptic connection to the common activity pattern, that is, imbalances drive balanced responses. Furthermore, there is no corresponding feedback from the common pattern onto the differential pattern. Balanced responses do not drive imbalances, nor does the differential pattern act on itself-imbalances do not drive further imbalance.

Thus the network of Figure F–3D, which appears to be fully recurrent when viewed in terms of the neurons, can be seen to have a hidden feed-forward structure when viewed in terms of differential and common activity patterns (it is hidden in the sense that it is not readily apparent in the synaptic connectivity of the network). This feed-forward pathway allows one activity pattern to excite the other without feedback (Figure F–4). The amplification driven by this "hidden" feedforward connection occurs with little dynamical slowing, whereas amplification as a result of a selfexcitatory loop is achieved at the cost of slowing of the dynamics. This description is mathematically precise when the relationship of a neuron's firing rate to its input (see Box F-2) can be taken to be linear, and it provides a useful intuition for understanding this type of network behavior more generally.

The strength of the amplification depends on two factors. One is the strength of the feed-forward connection from the differential to the common pattern, which is given by the sum of the excitatory and inhibitory synaptic strengths. The other is the strength of any remaining feedback loops. If we assume that inhibition is stronger than excitation, this results in a loop by which the common pattern inhibits itself (Figure F–4),

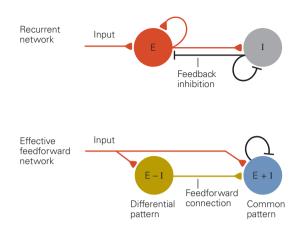

Figure F-4 An excitatory/inhibitory recurrent circuit is equivalent to a feed-forward circuit from a differential pattern (E-I) to a common pattern (E+I). The input to E in the recurrent circuit becomes equal input to both the E-I and E+I patterns. The inhibitory loop within the E+I pattern arises if the inhibitory projections are stronger than the excitatory.

because raising both excitatory and inhibitory rates produces a net inhibition of both the excitatory and inhibitory populations. This self-inhibition of the common pattern suppresses rather than amplifies responses; its strength is given by the difference between excitatory and inhibitory synaptic strengths. Thus the strongest amplification arises when both excitation and inhibition are strong but reasonably balanced.

This form of amplification can occur for each of many different spatial patterns of activity in a network of many neurons. In each spatial pattern an imbalance of excitatory and inhibitory activity can provide feedforward drive to common excitatory and inhibitory activity, with different spatial patterns having different strengths of this drive and thus different degrees of amplification. This mechanism has been proposed to underlie observations of spontaneous activity in the primary visual cortex of anesthetized cats (that is, activity in the absence of a visual stimulus).

Despite the absence of a visual stimulus, spatial patterns of activity resembling responses to structured visual inputs make a larger contribution to the overall spontaneous activity than patterns unrelated to these visual responses. If we think of spontaneous activity as being driven by unstructured inputs to the visual cortex that equally drive many different patterns, then the patterns that resemble visually driven responses are being amplified by the visual cortical circuit more than other patterns. What is the mechanism underlying this amplification?

Preliminary analysis suggests that the dynamics of the amplified patterns are not significantly slowed. In a model network with balanced excitatory and inhibitory connections that preferentially target cells with similar orientation selectivity, the spatial patterns that resemble visually driven responses have the largest effective feed-forward weights and so are amplified relative to other spatial patterns, without dynamical slowing, by the mechanism shown in Figure F–3D. This provides a possible explanation for the amplification of activity patterns that resemble visual responses in the absence of a visual stimulus.

Paradoxical Effects in Balanced Recurrent Networks May Underlie Surround Suppression in the Visual Cortex

In this section we discuss another effect that can arise in networks in which excitation and inhibition are both strong but relatively balanced. We consider a network that satisfies two criteria.

First, the excitatory recurrence is strong enough to make the excitatory network unstable by itself. That is, if the network is at a stable fixed point, and if inhibitory firing rates were kept frozen at their fixed-point levels, then after small perturbations of excitatory firing rates the excitatory network would drive itself even further away from its fixed-point rates. Second, feedback inhibition (inhibition driven by the excitatory cells) stabilizes the network. A slight change in excitatory firing rates drives a sufficient change in inhibitory firing rates to push the excitatory rates back to their fixed-point levels, despite the tendency of the excitatory network to "run away" on its own.

We refer to a network meeting these two criteria as an *inhibition-stabilized network*. The strong recurrent excitation received by excitatory cortical neurons and the instability of cortical activity when inhibition is blocked suggest that cortical circuits may indeed be stabilized in this way.

Inhibition-stabilized networks provide a possible explanation for a paradoxical experimental observation. The region of visual space within which an appropriate visual stimulus can elicit a response in a neuron in the primary visual cortex (V1) is known as the center region of the cell's receptive field. For many V1 neurons, increasing the size of the stimulus so that it also covers the surrounding region (the *surround*) reduces the response, a phenomenon known as *surround suppression*. However, a stimulus covering only the surround and not the center yields no response.

It is believed that stimulation of the center of a neuron's receptive field drives external excitatory input relayed from the eyes to both excitatory and inhibitory neural populations in the local cortical circuit, whereas a surround stimulus excites neighboring regions of cortex that send excitation more strongly to the inhibitory population within the local circuit. We might therefore expect that a stimulus in the surround should increase firing in the local inhibitory population, which in turn would suppress responses in the excitatory population.

Instead, experiments by David Ferster and colleagues indicate that a surround stimulus reduces both the excitation *and* the inhibition that a V1 neuron receives. That is, surround suppression is actually mediated by a reduction in the excitation of a cell, which has a larger effect than a concurrent reduction in inhibition. The reduction in inhibition suggests that the firing rate of the inhibitory population, like that of the excitatory population, is reduced by the surround stimulus, and this has been directly confirmed by Xue-Mei Song and Chao-Yi Li. Thus we arrive at the paradoxical result: A surround stimulus that is believed to drive external excitation to an inhibitory population causes a net decrease in the inhibitory population's firing rate.

This paradox can be explained by the presence in the cortex of strong recurrent excitation that is stabilized by inhibition, as shown in a model constructed by Misha Tsodyks and colleagues in a different context. The inhibitory neurons receive such strong drive from the excitatory neurons that their activity is determined more by the excitatory neurons than by any external input.

To see this, consider an inhibition-stabilized network composed of two populations of neurons, one excitatory and the other inhibitory (as in Figure F–3D), each initially firing at steady rates in response to a constant center stimulus (Figure F-5A). Adding a surround stimulus provides additional excitation to the inhibitory neurons from external sources. This transiently increases inhibitory neurons firing (Figure F–5B), which in turn lowers the firing rates of the excitatory neurons in the network (Figure F–5C), causing a withdrawal of recurrent excitatory input to the inhibitory neurons. Precisely when the network is inhibitionstabilized, this withdrawal of recurrent excitatory input to the inhibitory neurons exceeds the increase in excitation from external sources that started the process, so that the ultimate result, paradoxically, is that inhibitory firing rates are also lowered (Figure F–5D).

It is natural to think that, with inhibitory firing rates lowered, excitatory firing rates should then rise back above their initial levels, but this does not occur. To understand this we must understand one more point about an unstable excitatory subnetwork. Recall that an increase in excitatory firing recruits so much extra

recurrent excitation that, in the absence of changes in inhibitory firing, it would drive excitatory firing still higher. So too a decrease in excitatory firing withdraws so much recurrent excitation that excitatory firing rates would fall still lower in the absence of changes in inhibitory firing. The lowering of inhibitory firing rates decreases feedback inhibition, thus compensating for the deficiency of excitation and so stabilizing the lower firing rates of the excitatory population. The network thus arrives at a new stable fixed point in which both excitatory and inhibitory cells have lower firing rates than they did before additional external excitation was added to the inhibitory population.

This paradoxical result, in which adding excitatory input to the inhibitory cells results in a decrease in their steady state firing rate, is actually another instance of a hidden feed-forward connection by which a small differential or imbalance between excitation and inhibition can drive a large common response of both excitation and inhibition. In the present case the addition of excitatory input to the inhibitory cells drives a negative imbalance, which in turn drives a large negative common response, that is, a decrease in both excitatory and inhibitory rates. However, the increase in input also directly drives an increase in inhibitory firing rates. Thus there are two competing effects on inhibitory firing. The instability of the excitatory subnetwork turns out to be precisely equivalent to the condition in which the feed-forward effect is larger than the direct input effect, so that the net effect is a decrease in inhibitory firing rates.

The effect shown in Figure F–5 matches the observations we described earlier. When a stimulus in the receptive field surround results in additional excitatory input to inhibitory neurons, both the excitation and the inhibition in the recorded neurons is reduced. This finding and the theoretical analysis of it (only a portion of which is discussed here) provide strong evidence that the cortex operates in a regime in which recurrent excitation by itself is strong enough to be unstable but is stabilized by recurrent inhibition.

Recurrent Networks Can Model Decision-Making

As a final example of network modeling, we turn to circuits that select between different behaviors, that is, circuits that make decisions. Suppose the driver of an automobile needs to decide whether to turn right or left. Assume that there are two populations of excitatory neurons, one active when the decision is a right turn, the other when it is a left turn. Under some circumstances no decision needs to be made, so neither population should be highly active.

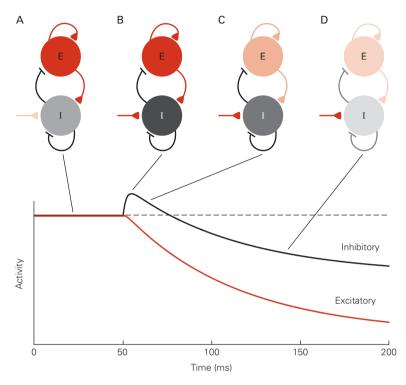

Figure F–5 Sequence of events following addition of a surround stimulus to a center stimulus in an inhibition-stabilized network model of primary visual cortex. The circuit consists of a population of excitatory neurons (E) that recurrently excite one another, and a population of inhibitory neurons (I) that recurrently inhibit one another (red/pink synapses are excitatory, black/grey synapses are inhibitory). The excitatory cells excite the inhibitory neurons, which in turn provide feedback inhibition to the excitatory cells. Stronger colors indicate higher levels of activity of a neuron or synapse. At all times the network receives a steady input driven by a steady center stimulus (not shown). The plot below is a continuous-time plot of excitatory and inhibitory firing rates. The points in time at which conditions A–D occur are indicated. (Adapted, with permission, from Ozeki et al. 2009.)

- A. The circuit before the addition of the surround input. The populations are firing at steady rates in response to the center stimulus. The surround input is not yet activated.
- **B.** After the surround input is activated at 50 ms, inhibitory firing rates initially increase.
- **C.** This additional inhibitory input drives down excitatory firing rates, resulting in withdrawal of recurrent excitation from both excitatory and inhibitory neurons and a corresponding decrease in inhibitory firing rates.
- **D.** When the network is inhibition-stabilized, this withdrawal of recurrent excitation to the inhibitory neurons is larger than the surround-induced increase of external excitation. Thus, in the end the inhibitory neurons receive less excitation than they did initially, and accordingly their firing rate is decreased.

A decision can be biased or unbiased by sensory input. If, for example, the sensory stimulus is a road sign that says "turn left," the sensory input should bias the decision toward a left turn. If the sensory stimulus is an obstacle in the middle of a three-lane highway, there is a need to turn but the direction may be arbitrary. In this case the sensory input should evoke a decision without biasing it. Between these extremes, inputs may provide a range of biasing effects.

To model decision-making in this context we follow the work of X. J. Wang, who has modeled decisionmaking circuits extensively. A network model of the kind of decision-making described above must have the following properties. First, in the absence of relevant sensory stimuli there should be a stable pattern of spontaneous activity corresponding to no decision. Second, a sensory stimulus requiring a decision should eliminate or destabilize the no-decision state and introduce two new stable firing patterns corresponding to the two possible actions. Third, sensory stimuli should be capable of biasing the outcome so that one of these decision states is more likely to occur than the other.

In our model different decision states are represented by two recurrently connected networks of excitatory neurons, both of which excite a single population of inhibitory neurons that return feed-back

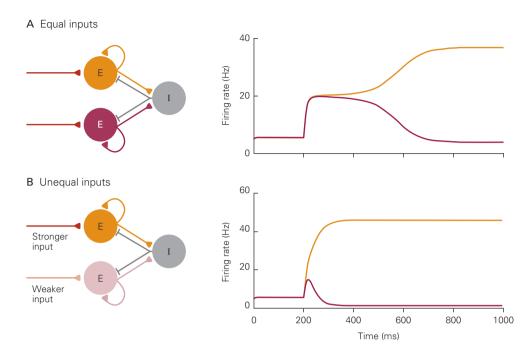

Figure F-6 A decision-making network. Two excitatory populations of neurons are active during two different decisions. An inhibitory population receives excitation from both excitatory populations and returns inhibition to both of them. A stimulus is presented at 200 ms. Before this time the network is in the no-decision state, in which excitatory populations have low firing rates.

A. In response to an unbiased stimulus the firing rates of both populations initially rise but then separate. The firing rate of the orange population ends up at a high value because small

random fluctuations (too small to see) raise it slightly higher than the firing rate of the purple population. This small difference was then amplified by the network, leading to a large difference in the two rates. Ultimately, only the firing rate of the orange population remains high, corresponding to the decision.

B. A stimulus biased in favor of the orange population generates a larger input to one excitatory population than the other. Note that the decision state is reached more rapidly than in the case of equal inputs (part A).

inhibition to both of them (Figure F–6A). In the absence of sensory stimuli the network stays in a no-decision state in which the neurons have low activity. In this state we assume that the neurons have a low level of input, and their activity reflects an equilibrium involving this input, recurrent excitation, and feedback inhibition. A stimulus that induces a decision takes the form of excitatory drive to both excitatory populations of the network.

When there is no bias favoring one decision over the other, the inputs to the two excitatory populations are equal. Nevertheless, the model does make a decision—the firing rate of one population rises to and remains at a high level, while that of the other population falls back to a low firing rate after an initial rise (Figure F–6A). This occurs because the stimulus-generated inputs force both excitatory networks away from their no-decision firing rates. With the no-decision state eliminated, only two stable states remain

available to the system, each corresponding to a different decision. One population ends up at a higher rate because small random fluctuations in the firing rates happen to favor that group (a small amount of noise was added to the model to generate these fluctuations). As a result of the fluctuations, each decision occurs 50% of the time.

When the stimulus is biased in favor of one population, the input to that population is higher than the input to the other. As a result, the firing rate of the favored population rises and remains high, while that of the other population falls after a brief and small rise (Figure F–6B). A strong-enough stimulus bias will produce the favored decision almost 100% of the time.

The latency from the time of the stimulus to the time a decision occurs can be determined by examining the divergence between the firing rates of the two neuronal populations. A decision is made more rapidly when the stimulus is biased than when it is unbiased (Figure F–6). This situation is similar to what is observed in the experiments on perceptual decision-making. In these experiments a monkey is trained to report the perceived direction of dots that move in many different directions on a screen. The monkey's performance depends on the coherence of motion of the dots. On most trials the dots have an overall tendency to move in one of two possible directions, introducing a type of stimulus bias. In some trials the coherence is zero, but the monkey still has to choose a direction of motion from these two possibilities. This situation is analogous to that shown in Figure F–6A.

There is experimental evidence that neural populations representing the two choice possibilities may be located in the posterior parietal cortex, specifically the lateral intraparietal area. Neurons recorded in this area by Michael Shadlen and collaborators during perceptual decision experiments involving moving dots behave like the model neurons in Figure F–6. Neural activity is initially driven by the sensory stimulus but then increases for one decision and decreases for the other. The final decision is preceded by a ramping activity that is relatively slow in the case of zero coherence of motion of the dots. This may be an indication of the existence of a period during which fluctuations are accumulating until a decision is made.

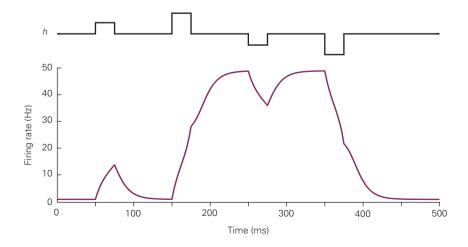

How does the model shown in Figure F–6 work and how was it constructed? The model relies on two key elements: bistability and inhibition-mediated competition between the two populations of excitatory neurons. Bistability is the ability of a network to sustain activity corresponding to either of two different states, typically one with a low rate of firing and one with a high rate. Persistent firing at a high rate is made

possible by strong recurrent excitation. Bistability requires the level of activity of a neuron to depend on its recurrent input in a nonlinear way. In the example of Figure F–6 the nonlinearity is assured by a sigmoidal neuronal response curve that makes the firing rate relatively insensitive to changes in input both at low firing rates (when mean voltage is well below threshold) and at high firing rates (when rates saturate) but highly sensitive at intermediate firing rates. At an intermediate level of firing the high sensitivity to changes in input renders the excitatory feedback unstable, forcing the network to high or low firing rates. At high or low firing rates the excitatory feedback becomes stable because of the weakened neuronal sensitivity, allowing a stable firing rate.

In a bistable network low and high firing rates are stable in the presence of small transient input pulses. Even if these transient inputs modify the firing rate of the network, the firing rate returns to its initial state after the input pulse terminates. However, larger input pulses can induce transitions from one firing rate to the other (Figure F–7).

The other crucial component in the model is inhibition. The decision model in Figure F–6 consists of two populations of excitatory neurons, each of which can be bistable, and an inhibitory population that is driven by both excitatory populations and reciprocally inhibits both of them. The purpose of the inhibitory population is to avoid the state in which both excitatory populations fire at high rates, which would correspond to making both decisions at once. This state is avoided by introducing sufficiently strong inhibition of the two excitatory populations. The resulting model is described mathematically in Box F–3. It and models

Figure F-7 A bistable network can alternate between two different states. The network starts in a low firing state. The first input pulse is too small to induce a transition from this state, but the larger second pulse flips the network into the high firing state. The third pulse is again too small to induce a transition, but the final pulse flips the network back to the low firing state.

Box F-3 The Decision Model

In the decision network r_a and r_b denote the firing rates of the excitatory populations a and b, each representing a unique decision, and r_I is the firing rate of an inhibitory population. As in Figure F–6A, we assume for simplicity that there is no excitatory coupling between the excitatory populations and that each receives identical input from the inhibitory population.

The equations of the model are:

$$\tau \frac{dr_{a}}{dt} = -r_{a} + F(w_{EE}r_{a} - w_{EI}r_{I} + h_{a})$$
 (F-4

$$\tau \frac{dr_{\rm b}}{dt} = -r_{\rm b} + F(w_{\rm EE}r_{\rm b} - w_{\rm EI}r_{\rm I} + h_{\rm b}).$$
 (F-5)

A small amount of random (white) noise is added to the right side of these equations. To avoid having a third differential equation for inhibitory firing rates, we use the approximation that the inhibition responds instantaneously and assume that r_1 is proportional to the sum of the excitatory rates r_a and r_b .

Without input $(h_a = h_b = 0)$ the firing rates of the two excitatory populations are equal and low. As a result, neither action is preferred or taken. This is the same nodecision state seen during the initial 200 ms period of the simulations in Figure F–6.

To induce a decision we introduce excitatory inputs corresponding to a sensory stimulus. Sufficiently large but equal inputs ($h_a = h_b > 0$) result in two stable states that correspond to the two decision states, $r_a > r_b$ or $r_a < r_b$. The state corresponding to the previous nodecision outcome has now disappeared.

To introduce a bias into the decision, we make $h_{\rm a}$ and $h_{\rm b}$ different. For example, if $h_{\rm a}$ is significantly larger than $h_{\rm b}$, only the stable state $r_{\rm a} > r_{\rm b}$ survives. For smaller biases there are regimes in which two stable states correspond to the two decisions, but the system is more likely to enter one stable state than the other.

like it provide an elegant way of simulating decision making, including such features as the time required to make a decision and the frequency of errors.

lateral, of amygdala, 1084, 1085f, 1086f	888–891	Odor coding, in invertebrates, 722
of neuron, 73f	dorsal premotor cortex in, 890-891	Odorants. See also Olfaction
Nucleus accumbens neurons	mirror neurons in, 888–889, 889f,	definition of, 713
dopamine in, 1105-1106, 1108f	890f	detection of large variety of, 712
glutamate in, 1108f	Observer model, 757, 759f	receptors for
Nucleus ambiguus, 1025f, 1027–1028	Obsessive-compulsive disorder (OCD),	combinations encoding, 715–716,
Nucleus of solitary tract, 1025f, 1026–1027	1419–1420. See also Anxiety	716f
in central autonomic network, 1069,	disorders	in mammal, 714–715, 715f
1071f	basal ganglia-thalamocortical circuits	OFF cells, 585–586, 592
forebrain projections of, 1069	in, 997	Off-center, 564, 566f
functions of, 1069, 1071f	treatment of, 1421–1422	Ogawa, Seiji, 427
Nucleus raphe magnus, in pain control,	Obstructive sleep apnea, 1152	Ohmic channel, 107, 107f
548, 548f	Occipital lobe, 342, 342f	Ohm's law, 136, 148, 1122b–1123b, 1530
Nudo, Randy, 856–858, 859f	function of, 10	in axoplasmic resistance, 144
Numa, Shosaku, 201	structure of, 9f, 10, 11f	on conductance, 1526
Numb, in neurogenesis, 1191–1192	Occludin, 1566–1567, 1569f	in single ion channels, 105, 105f
Nyberg, Lars, 1449	Occlusion	Oil–water partition coefficient,
Nystagmus, 923, 1538	of anterior choroidal and penetrating	permeability coefficient of, 1567,
horizontal, 1538, 1539f	arteries, 1556–1557	1570f
horizontally directed, on lateral gaze,	of carotid artery, 1557	Ojemann, George, 13
1538	of middle cerebral artery, 1553f	Olfaction, 449, 450f, 712–726
optokinetic, 924	Occlusive stroke, 1554	behavior and, 721–726
pendular, 1538	Octopus cells, 686–689, 688f–689f	evolution of strategies for, 725–726
rhythmical, 1538	Ocular counter-rolling response, 923	odor coding and, invertebrate, 722
right-beating, 923	Ocular dominance columns	olfactory system anatomy in, insect v
rotatory, 1538	brain-derived neurotrophic factor on,	vertebrate, 722–724, 723f
unilateral vestibular hypofunction in,	1271–1272	
31		stereotyped, nematode, 724–725, 725f
931, 932f	early life experience on architecture of,	726f
vertical, 1538	1263–1264, 1265f, 1266f	disorders of, 721
vestibular, 923, 924f	experimental induction of, in frog,	odorant detection by, breadth of, 712
	1266–1267, 1269f	olfactory acuity in, 721
O	extent of, determinants of, 1264–1267,	olfactory pathway to brain in, 716–721
.1 1100	1269f	nose odorant encoding by dispersed
ob gene, 1100	inputs from eyes to, 1263, 1263f	neurons in, 716–717, 717f
<i>ob/ob</i> mouse, 1100	modification of critical period for, 1281	olfactory bulb in
Obesity, 1100	plasticity of, critical period for, 1269,	information transmission to
Obesity (ob) gene, 1100	1270f	olfactory cortex by, 720, 720f

Olfaction, olfactory pathway to brain in,	KcsA K ⁺ channels, 115f, 116–119, 118f, 120f	on anticipation
olfactory bulb in (Cont.):	in resting nerve cells, ion conductance in,	of consequences of decisions, 407–408,
olfactory cortex output to higher	130–131, 132f	407f
cortical and limbic areas in, 721	Open-loop control, 754–756, 755f	of rewards, 408–409, 408f
organization of sensory inputs to,	Operant conditioning, 1454, 1457	decision making in, impaired, 407
717–719, 718f, 719f	associating behavior with reinforcing	Orbitofrontal circuit, lateral, 991 Orbitofrontal cortex lesions, on odor
olfactory receptor proteins in, 713–716 odorant receptors in, 714–715, 715f	event in, 1456–1457 vs. classical conditioning, 1454	discrimination, 721
receptor combinations encoding	Operculum, 342, 343f, 351f	Ordinal scales, 453
odorants in, 715–716, 716f	Ophthalmic artery, 1550, 1551f	Organ of Corti, 657f
sensory neurons in, 713–714, 713f, 714f	Opiate receptors, 549, 549t, 550–552	functional anatomy of, 660–663,
pheromone detection in, 712	Opiates, 1106t. See also Drug abuse	661f–663f
on behavior, 721–722, 722f	mechanism of action of, 550-552, 551f	hair bundles in, 662-664, 662f, 663f
Olfactory acuity, 721	physiology of addiction to, 1106-1108,	hair cells in, 661, 661f-663f
Olfactory bulb	1108f	in hearing, 661–664, 661f
glomeruli in, 717–718, 718f, 719f	side effects of, 552	Organelles, membranous, 72
interneurons in, 717, 717f	tolerance, dependence, and withdrawal	Organic mental illness, 1517
odor responses in, 717–718, 719f	mechanisms of, 1109–1110	Organizer region, on neural plate
organization of sensory inputs to, 717–719, 718f, 719f	Opioid peptides	development, 1168–1169, 1168f
Olfactory cortex	classes of, 549, 550f endogenous, 549, 549t, 550f	Organizing center signals in forebrain, midbrain, and hindbrain
definition of, 720	mechanism of action of, 550–552, 551f	patterning, 1171–1172,
information transmission to, by olfactory	side effects of, 552	1171f–1173f
bulb, 720, 720f	Opioid receptors, 1107–1108	in rostrocaudal neural tube patterning,
output to higher cortical and limbic areas	endogenous, 549, 549t, 550–552	1171–1172, 1171f–1173f
of, 721	Opioids, 298t	Orientation
Olfactory epithelium	tolerance and addiction to, 552	cerebellum in, 954, 964f
anatomy of, 713-714, 713f, 714f	Opsin, 582, 586f	to environment, visual inputs for, 947f,
organization of sensory inputs in,	in cones, 583	949
716–717, 717f	Optic ataxia, 873	lack of (disorientation), 1534
Olfactory nerve (CN I), examination for	from dorso-dorsal stream injury,	local, computation of, 602
function of, 1536–1537	417–418	in mental status examination, 1534
Olfactory receptor proteins, 713–716 odorant receptors in, 714–715, 715f	from parietal cortex injuries, 397, 398f Optic atrophy, 1537	postural, 936 in anticipation of disturbance to
receptor combinations encoding	Optic chiasm	balance, 943
odorants in, 715–716, 716f	axonal crossing in, 1227	on center of mass location, 936
sensory neurons in, 713–714, 713f, 714f	growth cone divergence at, 1221–1224,	integration of sensory information in,
Olfactory system anatomy, 713–714, 713f	1223f, 1224f	943–951
insect vs. vertebrate, 722–724, 723f	Optic disc, 578f, 580–581	vs. postural equilibrium, 936
Oligodendrocyte myelin glycoprotein	Optic disk swelling, 1537	for sensation interpretation, 941–943
(OMgp), 1292, 1293f	Optic nerve (CN II), 1020f, 1022f	for task execution, 941
Oligodendrocytes, 26, 27f, 1190	examination for function of, 1537	sensory signals in internal models for
functions of, 88	signaling pathways regulating axon	optimization of, 950–951, 952f
loss of, after brain injury, 1300–1301	regeneration in, 1291, 1291f	sexual, 1307
transplantation of, for myelin restoration,	Optic neuritis, 1537	sexually dimorphic behavior in,
1301, 1302f Olivocochlear neuron	pupillary response in, 1531, 1539f Optic radiation, 559, 562f	1321–1325 spatial, sensorimotor transformations in,
feedback loop in, 693, 695f	Optimization, 1598	744, 745f
in lateral, 694, 695f	Optokinetic eye movements, 895	touch, neurons sensitive to, 518, 520f
medial, 693–694, 695f	Optokinetic nystagmus, 924	Orientation columns, in primary visual

prosodic cues for, 1358–1359	Sex hormones, 1306	definition of, 1447
Sequential synaptic pathways, from	Sex-linked inheritance, 42–43	medial temporal lobe in, 1447
Hebbian plasticity, 1594f, 1598–	Sex-reversed male, XX, 1307	Sham rage, 1081, 1082f
1599	Sexual arousal sensations, 488	Shape
Serial order problem, of motor behavior,	Sexual differentiation, 1306–1326	cortical representation of, in visual
423	behavioral differences in, 1306	search, 471f, 618, 618f
140	Scharloral afficiences III, 1000	Jearch, 17 11, 010, 0101

object geometry in analysis of, internal	neuron type on, 33, 34f	inherited
models of, 571f, 574f, 604–607,	output component in, 35	muscular dystrophies, 320-324
605f-607f	rapid, ion channels in, 101	(See also Muscular dystrophies)
recognition of, inferotemporal cortex in,	receptor potential in, 31, 32f, 33t	myotonia congenita, 326, 326f
402, 403f	resting membrane potential in, 30	periodic paralysis, 324–326, 325f, 326f
Shell shock, "fight-or-flight" response in,	sensory to motor transformation in, 35, 36f	voltage-gated ion channel genetic
1066–1067	signal types in, 30	defects in, 324
		Skin
Shellfish poisoning, amnestic, 1134–1135	synaptic potential in, 31, 33t	
Shereshevski, 1458	trigger zone in, 31–33, 32f	mechanoreceptor types in, 480t, 482, 483f
Sherrington, Charles	Signaling endosomes, 1204	thermal receptors in, 485–486
on blood flow and brain metabolism, 426	Silent interval, 1137	Skin temperature changes, thermal
cellular brain studies of, 8–9	Silent nociceptors, 532	receptors for, 485–486, 487f
on habituation, 1463	to spinal cord dorsal horn, 534, 534f	Skinner, B.F., 371, 1355–1356, 1456
on motor units, 307, 768	Silent synapses, 1495, 1496f	Sleep, 1140–1151
peripheral nerve fiber classification by,	Simon, Herbert, 372	aging on, 1150, 1150f
477, 478f	Simple cells, 604–606, 605f	brain rhythmic activity in, 1148, 1149f
on proprioceptive signals, 804, 823	Simple partial seizures. See Focal seizures	breathing in, unstable, 1034-1035, 1035f
on receptive field, 564, 565f	Simple phobias, 1419. See also Anxiety	circadian rhythms in, 1144-1146, 1145f,
on sensory information in movement	disorders	1146f
regulation, 790	fear circuitry in, 1421	clock for, and nuclear transcription
sensory studies of, 475	genetics of, 1420	factors, 1145f, 1146–1147, 1149f
spinal circuitry experimental model of, 795	treatment of, 1421	EEG of
on stance phase of locomotion, 823	Simultanagnosia, 1536	local and long-range circuits in, 1148
on stretch reflex, 792–794, 795	Single-neuron models, 1602–1605	stages of, 1141, 1142f
	=	9
on synapses, 177	focus of, 1602	functions of, 1140
Sherrington's reflex arc, 1582	integrate-and-fire model in, 1602, 1603b,	physiological changes in, 1141, 1143f
Shik, Mark, 825	1603f	REM and non-REM periods in,
shiverer (shi) mutant mice, 91b, 91f	intrinsic and extrinsic signals in neuronal	1141–1144
Shock	inputs in, 1603f, 1605	EEG of, 1141, 1142f
ischemia or infarction from, 1561–1562	number and synchrony of synaptic	non-REM stages in, 1141, 1142f, 1143f
shell, "fight-or-flight" response in,	inputs in	physiological changes in, 1141, 1143f
1066–1067	graded sensitivity to, in noisy	species differences in, 1150-1151
spinal, 809	conditions, 1503f, 1604-1605	ultradian rhythms in, 1144–1146
Short arm, 63	sharp threshold sensitivity to, in quiet	brain stem control of, 1142f, 1147-1148,
Short circuit, 137, 139f	conditions, 1602–1604, 1603f	1148f
circuit analysis for, 1528	spike synchronization in, 1602	Sleep apnea, 1152, 1153f
Short-circuiting effect, 225	Single nucleotide polymorphism (SNP),	breathing in, 1035f
Short circumferential branches, 1557	60b, 64	central, 1152, 1153f
Short-range stiffness, 780	Single-photon emission computed	obstructive, 1152
Shortening contraction, 779, 784	tomography (SPECT)	Sleep attacks, 1152–1153
		±
Shunting effect, 225	of brain blood flow, 427f	Sleep deficit, 1145–1146, 1146f, 1152
Si, Kausik, 1476, 1477f	for seizure focus localization, 1133	Sleep disorders, 1151–1156
Sib pair analysis, 60b	Sirtuins, 1333	circadian rhythm, 1156
Sideband inhibition, in stellate cells, 689	Site-directed mutagenesis, in ion channel	epidemiology of, 1151
Sides, 339f	structure studies, 112–113	excessive daytime sleep, 1152
comparison of, 1543–1544, 1545f	Size constancy, in object identification, 627,	insomnia, 1151
Sign language, 678	629f	narcolepsy, 1152–1155, 1154f, 1155f
Signal detection theory, 454, 456b–457b,	Size-weight illusion, 761, 761f	parasomnias, 1151, 1155–1156
456f, 457f	Skelemins, 777, 778f-779f	pathophysiology of, 1151
Signal pathways, 23	Skeletal mechanoreceptors, 480t	periodic leg movements, 1155
Signaling, 29–35. See also specific types	Skeletal muscle, 307	restless leg syndrome, 1155
action potential in, 31	of N ⁺ channel, impaired, 324, 325f	sleep apnea, 1152, 1153f
action potential in, all-or-none, 23f, 32f,	Skeletal muscle cells	Sleep drive, 1145–1146, 1146f
33–35, 33t	motor neuron activity on biochemical	Sleep paralysis, 1153–1154
	_	Sleep spindles, 1120f, 1129
depolarization and hyperpolarization	and functional properties of,	
in, 31	1238–1239, 1240f	Sleep talking, 1155–1156
dynamic polarization in, 30	types of, 1238	Sleep-wake cycle, 1144–1146, 1145f, 1146f
functional components of, 29–30, 30f	Skeletal muscle diseases, 320–326	circadian rhythm in, 1041
ion channels in, 30	acquired, 320	monoaminergic and cholinergic neurons
Na ⁺ -K ⁺ pump in, 30	dermatomyositis, 320	in, 1041, 1045f

vestibulocerebellar lesions on, 969, 970f

Sleep walking, 1155–1156	Smooth-pursuit system, 895–896, 896f	Somatosensory cortex, 362f, 367f
Sleepiness, 1145–1146, 1146f	smoothened, 1174–1175	evoked potentials in, from hand
daytime, 1152	Snail, 1197	stimulation, 374f
Sliding filament hypothesis, 777	SNAP (soluble NSF-attachment protein),	in feelings, 1090–1092, 1090f
	280, 280f	lesions in, tactile deficits from, 524–526,
Slits, in axon growth and guidance,		
1222f-1223f, 1229, 1230f	SNAP-25, 278, 279, 279f, 280f	525f, 526f
Slow adapting (SA) fibers, 499, 500t	SNAREs	maps of
Slow axonal transport, 80, 83–84	in exocytosis, 278–281, 280f, 281f	hand, 379, 379f, 380f
Slow channel syndrome, 319	Q-, 278, 279f	human, 375–376, 376f
Slow-twitch motor units, 770, 771f	R-, 278	organization of, 364–365, 364f, 365f
Slow-twitch muscle fibers, 1240f	t-, 87, 278	primary, 364, 365f, 510, 512f
Slowly adapting receptors, 463	v-, 87, 278	secondary, 512f
Slowly adapting type 1 (SA1) fibers,	Snellen's chart, 1537	cognitive touch in, 518-522, 522f, 523f
499–501, 500f, 500t, 502f	Snout reflex, 1549	lesions to, 524–525
for grip control, 510, 511f	Social anxiety disorder (social phobia),	Somatosensory cortex barrels, 1182–1183,
for pressure and form, object, 504, 507f,	1419. See also Anxiety disorders	1184f
508	amygdala in, 1421	Somatosensory inputs. <i>See also specific types</i>
	, 0	
Slowly adapting type 2 (SA2) fibers, 499,	fear circuitry in, 1421	ambiguous information on posture and
500f, 500t, 501, 502	genetics of, 1420	body motion from, 949–950,
for grip control, 510, 511f	Social behaviors. See also specific types	950f
for shape and finger movements, 508	early experience on, 1260–1261, 1262f	Somatosensory maps, experience on, 1483,
in stereognosis, 503f, 508	neuropeptide receptors on, 54–55, 55f,	1484f
Slug, 1197	56f	Somatosensory system, 357–365, 475–495
SM proteins, 279, 279f	Social cognition, interaction with others	in cerebral cortex, 363-365, 364f, 365f,
Small hairpin RNA (shRNA), 48b	in, 422	373f
Small interfering RNA (siRNA), 48b	Social deprivation, early childhood	cranial and spinal nerves in, 488
Small-molecule neurotransmitters, 290–297	in humans, 1260–1261, 1262f	definition of, 475
acetylcholine, 291	in monkeys, 1261, 1262f	dermatomes in, 488, 489f
active uptake of, into vesicles, 295–297,	Social emotions, frontal and prefrontal	dorsal root ganglia in
296f	cortex in, 1088–1089, 1089f	central axons as body surface map in,
amino acid, 294	Social phobia, 1419. See also Anxiety	360, 361f
ATP and adenosine, 294–295	disorders	primary sensory neurons in, 476–477,
biogenic amine, 291, 292	Socially appropriate behavior, lateral	476f
catecholamine, 291–293, 293b	orbitofrontal circuit in, 991	sensory neurons of, 358, 360f
feedback regulation of, 292	SOCS3, on axon growth, 1291, 1291f	exteroception in, 475–476
norepinephrine, 292	Sodium channel. See Na ⁺ channel	interoception in, 476
synthesis of, 291–292	Sodium-potassium pump. See Na ⁺ -K ⁺	myotome in, 488
histamine, 294	pump	overall view of, 495
vs. neuroactive peptides	Sodium symporters (NSS), 304	pain in, 476
coexistence and co-release of, 300–301	Sokoloff, Louis, 426-427, 428b-429b, 428f,	peripheral nerves in, 477
differences in, 300	429f	peripheral somatosensory nerve fibers
overview of, 290–291, 291t	Sokolowski, Marla, 52–54, 54f	in, action potential conduction
packaging of, 290	Solitary nucleus, 1025f, 1026–1027	rates of, 477–479, 477t, 478f, 479f
